We present theoretical estimates of the inclusive prompt photon energy spectrum in direct decays of \( B \)-hadrons through the charged current processes \( B \rightarrow X_c + \gamma \) and \( B \rightarrow X_u + \gamma \), and the flavour changing neutral current (FCNC) processes \( B \rightarrow X_s + \gamma \) and \( B \rightarrow X_d + \gamma \) (here the subscript \( q \) on \( X_q \) denotes the quark flavour in the transition \( b \rightarrow q \)). It is argued that the various components in the inclusive spectrum can, in principle, be disentangled using the photon energy and flavour tagging the hadron(s) recoiling against the photon in \( B \)-decays, thereby providing a new technique to determine the CKM matrix elements \( |V_{cb}| \), \( |V_{ub}| \), \( |V_{tb}| \), and \( |V_{td}| \). In particular, the high energy part of the inclusive photon energy spectrum being dominated by the electromagnetic penguins could provide the first direct measurement of the CKM matrix element \( |V_{ts}| \). We quantify this by firming up predictions for the inclusive decays \( B \rightarrow X_s + \gamma \) in the standard model.

1. Introduction

Semileptonic \( B \)-decays have provided valuable information on the properties of the \( b \)-quark, in particular the Cabibbo–Kobayashi–Maskawa (CKM) [1] matrix elements \( |V_{cb}| \) and \( |V_{ub}| \) [2]. In this paper, we focus on radiative \( B \)-decays. We present a first estimate of the inclusive photon energy spectrum in the decays \( B \rightarrow X + \gamma \). With a high-resolution electromagnetic calorimeter and large enough \( B \)-meson sample, it should be possible to measure the prompt (hard) photon radiation spectrum in the weak decays of heavy quarks. Quite importantly, precision measurements of the inclusive and exclusive photon energy spectra in \( B \)-decays may provide new techniques to determine the CKM matrix elements. We elaborate this point on the example of the decay \( B \rightarrow X_s + \gamma \) which would determine the CKM matrix element \( |V_{ts}| \).

To get the inclusive photon spectra in \( B \rightarrow X + \gamma \), both the charged current (CC) radiative transitions \( B \rightarrow (X_c, X_u) + \gamma \), involving the basic couplings in the SM lagrangian [3], and the flavour changing neutral current (FCNC) processes \( B \rightarrow (X_s, X_d) + \gamma \), induced by the so-called electromagnetic penguins, have to be taken into account. The former decays are sensitive to the CKM matrix elements \( |V_{cb}| \) and \( |V_{ub}| \) as can be seen in table 1, where the dominant CC transitions at the quark level are listed together with their CKM matrix element dependence. The FCNC radiative decays \( B \rightarrow (X_s, X_d) + \gamma \), on the other hand, are essentially determined by the magnetic moment operators, whose Wilson coefficients are dominated by the top quark contribution in the processes \( b \rightarrow (s, \bar{d}) + \gamma + (g) \). This brings to the fore the dependence of the rates of the top quark mass \( (m_t) \) and the CKM matrix elements \( |V_{ts}| \) (for \( B \rightarrow X_s + \gamma \)) and \( |V_{td}| \) (for \( B \rightarrow X_d + \gamma \)) [4,5]. It follows that a precise measurement of the prompt photon energy spectra in \( B \) decays has, in principle, the potential of determin-

Table 1: CC radiative b-quark decays contributing to $B\rightarrow (X_c, X_u) + \gamma$ and their CKM matrix element dependent factors $K_n$.

We have used the photon energy spectra from the decays $B\rightarrow (X_c, X_u) + \gamma$ and $B\rightarrow (X_s, X_d) + \gamma$. Section 3 summarizes the results of the FCNC decays $B\rightarrow X_c + \gamma$ and $B\rightarrow X_d + \gamma$ [4,5]. The resulting branching ratios for the decays $B\rightarrow X_c + \gamma$ and $B\rightarrow X_d + \gamma$ and their dependence on the various parameters, including the CKM matrix elements, top quark mass, and the renormalization scale are also presented here. Finally, in section 4 we summarize the main features of the inclusive photon energy spectra presented in this paper. An estimate of the exclusive branching ratio $BR(B\rightarrow K^* + \gamma)$ is also given here.

2. CC radiative B-decays

The CC radiative decays $B\rightarrow X_c + \gamma$ and $B\rightarrow X_u + \gamma$ that we want to calculate are modelled after the quark decays given in Table 1. They represent single photon bremsstrahlung processes from all the charged fermion lines (leptons and quarks) evaluated in the spectator model. Note that we have neglected the so-called W-exchange two-body decays, since they are generally considered negligible in B-decays [7]. Also, there is no compelling evidence in the experiments calling for a revision of this opinion. The most convincing support in favour of the dominance of the spectator model contribution is the (near) equality of the charged- and neutral B-meson lifetimes, gotten indirect through the ARGUS and CLEO measurements of the semileptonic branching ratios [8]:

$$\frac{\tau_{B^+}}{\tau_{B^0}} = \frac{BR(B^+\rightarrow D^{(*)}\pi^0\ell^+\nu)}{BR(B^0\rightarrow D^{(*)}\pi^0\ell^-\bar{\nu})} = 0.96 \pm 0.14. \quad (1)$$

We now specify the approximations used in calculating the inclusive photon energy spectrum from the CC processes. First, we have left out the QCD corrections to the decays listed in Table 1. It is to be noted here that the renormalization group improvements of the effective four-Fermi interactions are known from analogous studies in the non-radiative B-decays and they could have been included without much ado. These improvements are, however, numerically not important [7,9,10]; also they represent only a part of the corrections. It is to be noted that the radiative semileptonic decays contribute more significantly to the CC radiative B-decays due to the smallness of the
electron and muon mass. Hence, the dominant (and non-trivial) corrections in CC decays are expected to arise from the leading QCD contribution to the semileptonic radiative decays, including real and virtual gluon bremsstrahlung processes such as \( b \rightarrow (c, u) e \nu_k + \gamma + g \), which, as far as we know, are not yet calculated. These corrections will be needed as the experimental precision on the inclusive photon energy measurements improve. For a first estimate, the CC processes listed in table 1 are quite adequate. However, it is well known that the QCD corrections to the electromagnetic penguins in the decays \( b \rightarrow (s, d) + \gamma \) are very important \([11]\). We of course keep these correction, both real and virtual, in the evaluation of the FCNC radiative decays \( B \rightarrow (X_s, X_d) + \gamma \) along the lines described in refs. \([4,5]\).

We have also left out the QED virtual corrections to the processes in table 1, as a result of which our calculations are ill-suited to describe the soft photon energy spectrum in radiative B-decays. There is no experimental interest in the soft photon spectrum either, since it is inundated by the initial state radiation (in \( e^+e^- \) production processes) and secondary photons from the pion and kaon decays produced in B-decays and in background processes. Depending on the experimental details, the photon energy spectrum above a certain threshold (say \( E_\gamma \geq 1.0 \text{ GeV} \) in the B-rest frame) should, however, be reliably given by the sum of the CC contributions in table 1 and the FCNC contributions discussed in the next section. With these remarks, we now proceed to outline the derivation of the inclusive photon energy spectrum in B-decays.

We define the kinematics of the CC radiative B-decays on the example of reaction \( n = 1 \) in table 1,\n\[
b(p_1) \rightarrow c(p_2) + d(p_3) + \bar{u}(p_4) + \gamma(k). \tag{2}\]

The fully differential decay width for a b quark decaying at rest reads as\n\[
\frac{d\Gamma_n}{2m_b} = \frac{(2\pi)^4}{2m_b} \delta^4(p_1 - p_2 - p_3 - p_4 - k)\]
\[
\times |M_n|^2 \frac{d\mu(p_2) \ d\mu(p_3) \ d\mu(p_4) \ d\mu(k)}, \tag{3}\]

where the sum over the final spin and colour factors and average over the initial spin and colour are implied. The symbol \( d\mu(p) \) defines the invariant measure for each particle in the final state, \( d\mu(p) = d^3p/ (2\pi)^32p^0 \). The spin- and colour-averaged matrix element squared can be expressed as\n\[
|M_n|^2 = 128\pi\alpha_{em} G_F^2 |A|^2 K_n. \tag{4}\]

Here \( K_n \) is a reaction dependent factor given in table 1 and the reduced matrix element squared \( |A|^2 \) is given below:
\[
|A|^2 = 2p_2 \cdot p_3 \left( \frac{Q_1^2}{p_1 \cdot k} p_4 \cdot k + \frac{Q_4^2}{p_4 \cdot k} p_1 \cdot k \right) + 2p_1 \cdot p_4 \left( \frac{Q_3^2}{p_2 \cdot k} p_3 \cdot k + \frac{Q_3^2}{p_3 \cdot k} p_2 \cdot k \right) - 4(Q_2 Q_3 p_1 \cdot p_4 - Q_1 Q_4 p_2 \cdot p_3) - p_2 \cdot p_3 \left( \frac{Q_1}{p_1 \cdot k} + \frac{Q_4}{p_4 \cdot k} \right) (B \cdot p_4 p_1 \cdot k - B \cdot p_1 p_4 \cdot k) - p_1 \cdot p_4 \left( \frac{Q_2}{p_2 \cdot k} - \frac{Q_3}{p_3 \cdot k} \right) (B \cdot p_3 p_2 \cdot k - B \cdot p_2 p_3 \cdot k) - \frac{1}{2} B^2 p_2 \cdot p_3 p_1 \cdot p_4, \tag{5}\]

with\n\[
B^2 = 2 \left( \frac{Q_1 p_4^4}{p_1 \cdot k} - \frac{Q_2 p_4^6}{p_2 \cdot k} - \frac{Q_3 p_4^6}{p_3 \cdot k} + \frac{Q_4 p_4^8}{p_4 \cdot k} \right), \tag{6}\]

and \( Q_i \) are the electric charges of the fermions. For the non-leptonic radiative decays (reactions 1–4 and 8–11 in table 1), they have the values \( Q_1 = Q_3 = -\frac{3}{2}, Q_2 = Q_4 = \frac{3}{2}, \) while for the semileptonic decays (reactions 5–7 and 12–14 in table 1), they have the values \( Q_1 = -\frac{3}{2}, Q_2 = +\frac{3}{2}, Q_3 = -1, Q_4 = 0 \). To get the photon energy spectra from these processes, the integration over the phase space has been done using a Monte Carlo programme. To avoid the collinear region which, due to the smallness of \( m_e \), is accentuated in the semileptonic decay involving the electron, \( b \rightarrow (u, c)e\nu_e + \gamma \), one could put a cone around the electron direction and exclude the \( (\gamma + e) \) collinear configuration. With the matrix element given in (5), this can be done for a given experimental setup. For the sake of this paper, we set the electronic radiative decay width equal to the muonic. We have compared the photon energy spectra in the CC b-quark transitions with the corresponding ones obtained in ref. \([12]\) and we are in agreement with their results. To get the photon energy spectrum from the B-hadron decays, however, one has to incorporate the wave...
function effects. The resulting CC spectra will be presented after we have described the wave function model being used.

The B-meson wave function model as applied to the FCNC decays is discussed in refs. [4,5]. This model has previously been used in the derivation of inclusive semileptonic distributions [13,14], where it is known to give a good description of the measured lepton energy spectrum. In this model the b-quark is given a non-zero momentum having a gaussian distribution represented by an a priori free (but adjustable) parameter, \( p_F \):

\[
\phi(p) = \frac{4}{\sqrt{\pi p_F^2}} \exp \left( -\frac{p^2}{p_F^2} \right), \quad p = |p|.
\]  

(7)

The energy-momentum constraint is imposed in the form

\[
W^2 = M_B^2 + m_\text{q}^2 - 2M_B \sqrt{p^2 + m_\text{q}^2},
\]

(8)

where \( M_B \) is the B-meson mass, \( W \), the effective mass of the b-quark, and \( m_\text{q} \), the mass of the spectator quark in the B-meson, \( B = b \bar{q} \). The mass of the decaying b-quark varies according to eq. (8). The photon energy spectrum from the decay of the B-meson at rest is then given by

\[
\frac{d\Gamma}{dE_\gamma} = \int_0^{p_{\text{max}}} \phi(p) p^2 dp \frac{d\Gamma_b}{dE_\gamma} (W, p, E),
\]

(9)

where \( \phi(p) \) is normalized as

\[
\int_0^\infty \phi(p) p^2 dp = 1.
\]

(10)

\( p_{\text{max}} \) is the maximum allowed value of \( p \), and \( d\Gamma_b / dE_\gamma \) is the photon energy spectrum from the decay of the b-quark in flight, having a mass \( W \) and momentum \( p \). This can be obtained by Lorentz boosting the b-quark decay spectrum at rest. The physical kinematic threshold in the problem and the energy–momentum constraint eq. (8) have to be respected. The dependence of the inclusive rates for both \( B \to X_u + \gamma \) and \( B \to X_d + \gamma \) on the wave-function parameter, \( p_F \), is negligible, though the photon energy spectra, very much like the lepton energy spectra in semileptonic B decays, are sensitive to its value. We take the best fit for \( p_F \) obtained from a fit of the ARGUS and CLEO inclusive lepton energy spectrum \( p_F = 0.30 \pm 0.09 \) GeV [15,16]. The branching ratio for the both the CC and FCNC radiative decays are calculated using the total B-decay width, \( \Gamma_{\text{tot}} \):

\[
\Gamma_{\text{tot}} = (r_u |V_{ub}|^2 + r_c |V_{cb}|^2) \Gamma_0,
\]

\[
\Gamma_0 = \frac{\lambda_{\text{eff}}^2 G_F^2}{192\pi^3}, \quad r_u \approx 7, \quad r_c \approx 3.
\]

(11)

The values of \( r_u \) and \( r_c \) include phase space and QCD corrections [7,17]. The dependence on the effective b-quark mass, \( \lambda_{\text{eff}} \) which enters as the fifth power in both \( \Gamma_{\text{tot}} \) and all the radiative decays considered here cancels to a very large extent in the respective branching ratios. Note that the spectra and all the decay rates are calculated directly in terms of the B-meson mass. The effective b-quark mass, entering in \( \Gamma_{\text{tot}} \) can also be expressed in terms of the B-meson mass and the parameter \( p_F \). A very good (numerical) functional dependence of \( \lambda_{\text{eff}} \) for the present model can be parametrized as

\[
\lambda_{\text{eff}} \approx M_B^2 - 2M_B p_F \cdot 1.28.
\]

(12)

In the numerical estimates, a number of quark and lepton masses and the CKM matrix elements are needed. For the CKM matrix, we always use the Wolfenstein parametrization [18]. The explicit form of this matrix and an update of the actual values of the CKM matrix elements can be seen in ref. [19]. Unless stated otherwise, the parameters used in our analysis are listed in table 2, and the others are taken from the PDG tables [20].

The inclusive photon energy spectra from the CC

| Table 2 |
|-----------------|-----------------|
| **Parameter**   | **Default value** |
| \( m_t \) (GeV)  | 140             |
| \( m_c \) (GeV)  | 1.68            |
| \( m_s \) (GeV)  | 0.50            |
| \( m_b = m_q \) (GeV) | 0.30           |
| \( \mu \) (GeV)  | 5.0             |
| \( \lambda^{(9)} \) (GeV) | 0.225        |
| \( p_F \) (GeV)  | 0.3             |
| \( |V_{us}| \)    | 0.041           |
| \( |V_{cb}| \)    | 0.041           |
| \( |V_{ub}| / |V_{cb}| \) | 0.14         |
| \( |V_{cd}| = |V_{ud}| \) | 0.220        |
| \( |V_{cd}| = |V_{ud}| \) | 0.975        |
radiative decays including the B-meson wave function effects are plotted in figs. 1a–1c, corresponding to the non-leptonic decays, semileptonic decays and their sum, respectively. In each of these figures, we show the contribution from the decays $B \rightarrow X_c + \gamma$, $B \rightarrow X_u + \gamma$ and their sum $B \rightarrow (X_c, X_u) + \gamma$, as well as the contribution from the FCNC processes $B \rightarrow X_s + \gamma$ and $B \rightarrow X_d + \gamma$ (discussed in the next section). We postpone a discussion of these spectra to section 4.

3. FCNC decays $B \rightarrow X_s + \gamma$ and $B \rightarrow X_d + \gamma$

We have already reported the calculations leading to the inclusive branching ratios for the FCNC decays $B \rightarrow X_s + \gamma$ and $B \rightarrow X_d + \gamma$, and the resulting inclusive photon energy spectra in a series of papers [4,5]. Since these papers are sufficiently detailed, we will restrict ourselves to recalling the salient features of this work necessary for the discussion here. We recall that the inclusive rates and spectra have been calculated in the framework of an effective theory with five quarks, obtained by integrating out the heavier degrees of freedom (top quark and $W^\pm$ bosons), by keeping only the operators with the lowest (mass) dimensions. To leading order in the small (weak)-mixing angles, a complete set of dimension-six operators relevant for the processes $b \rightarrow s + \gamma$ and $b \rightarrow s + \gamma + g$ is contained in the effective hamiltonian
\[ H_{\text{eff}}(b \to s\gamma) = -\frac{4G_F}{\sqrt{2}} \lambda_t \sum_{j=1}^8 C_j(\mu) \hat{O}_j(\mu), \quad (13) \]

where \( G_F \) is the Fermi coupling constant, \( C_j(\mu) \) are the Wilson coefficients evaluated at the scale \( \mu \), and \( \lambda_t = V_{tb} V_{ts}^\ast \), with \( V_{ij} \) being the Cabibbo–Kobayashi–Maskawa (CKM) matrix elements. Note that the operators \( \hat{O}_1, \ldots, \hat{O}_8 \) are the four-fermion operators, and \( \hat{O}_7 \) and \( \hat{O}_8 \) are the QED and QCD magnetic moment operators, respectively. Their definitions, matching conditions \( C_i(\mu) \), and the leading log perturbative QCD corrections giving \( C_j(\mu) \) with \( \mu \ll m_W \) can be seen in ref. [11]. We use the definitions and estimates of \( C_i(\mu) \) from Grinstein et al. in ref. [11]. Discussing the contribution of the bremsstrahlung diagrams \( b \to s + \gamma + g \), we recall that the diagrams associated with \( \hat{O}_7 \) vanish due to the colour structure. Also, the coefficient of the operator \( \hat{O}_8 \) gets suppressed after including QCD effects and its contribution can be neglected. The operators \( \hat{O}_3, \ldots, \hat{O}_6 \) get contribution only from operator mixing and are also numerically unimportant. Thus, the dominant contribution to \( B \to X_s + \gamma \) are due to the operators \( \hat{O}_2 \) and \( \hat{O}_7 \) (the electromagnetic penguin operator) which are defined as

\[ \hat{O}_2 = (\xi_L \gamma^\mu b_L) \left( \tilde{\xi}_L \gamma^\nu \bar{c}_L \right), \]
\[ \hat{O}_7 = (e/16\pi^2) \xi_a \sigma^{\mu\nu} (m_b R + m_s L) b_{\alpha} F_{\mu\nu}, \]
\[ L = \frac{1}{2} (1 - \gamma_5), \quad R = \frac{1}{2} (1 + \gamma_5). \quad (14) \]

Here \( e \) denotes the QED coupling constant. The coefficients \( C_2(\mu), C_7(\mu) \), obtained in the leading logarithm approximation (LLA) [11], and the corresponding coefficients at the scale \( m_W \) are listed below:

\[ C_2(\mu) = \frac{1}{2} (\eta^{-6/23} + \eta^{12/23}) C_2(\mu_W), \]
\[ C_7(\mu) = \eta^{-16/23} \left[ C_7(\mu_W) - \frac{29}{189} (\eta^{10/23} - 1) C_2(\mu_W) \right], \]
\[ C_2(\mu_W) = 1, \]
\[ C_7(\mu_W) = F_2(x), \quad (15) \]

with \( \eta = \alpha_s(\mu)/\alpha_s(\mu_W) \) being the ratio of the QCD coupling constants and \( x = m_s^2/m_W^2 \). The Inami–Lim function \( F_2(x) \) derived from the penguin diagrams is given by [21]

\[ F_2(x) = \frac{x}{24(x-1)^4} \left[ 6x(3x-2) \log x \right. \]
\[ \left. - (x-1)(8x^2+5x-7) \right]. \quad (16) \]

It is clear from eqs. (13), (15), (16) that a measurement of the inclusive branching ratio for \( B \to X_s + \gamma \) provides information on \( |V_{us}| \) and \( m_t \), given other parameters. Before we quantify this information there is one point, however, which we would like to stress here concerning the renormalization scale dependence of the QCD-improved Wilson coefficients in \( H_{\text{eff}} \) defined above. We recall here that the coefficients \( C_i(\mu) \) given in eq. (15), being LLA results, show a significant dependence on the renormalization scale \( \mu \). In the decays of \( B \)-hadrons, the b-quark mass suggests itself as a natural choice, i.e. \( \mu = m_b \), which is what has been used in the literature to determine the decay rates in \( b \to s + \gamma \) [11]. However, it is difficult to pin down the scale \( \mu \) that sharply. It is prudent to allow \( \mu \) to vary within some reasonable range. Following this argument, we shall vary \( \mu \) in the range \( m_W/2 \leq \mu \leq 2m_W \). As we shall see this is one of the dominant uncertainties in the electromagnetic penguin amplitudes.

The modifications that have to be implemented for the CKM-suppressed FCNC radiative decays \( b \to d + \gamma \) and \( b \to d + \gamma + g \) have been discussed in ref. [5]. We recall here that for the decays \( b \to s + \gamma (\pm g) \) the effective hamiltonian was written in the approximation where the CKM factor \( \lambda_\alpha = 0 \), which is reasonable since \( \lambda_\alpha \ll (\lambda_c, \lambda_t) \) (where \( \lambda_1 \equiv V_{tb} V_{ts}^\ast \)). For the decays \( b \to d + \gamma \) and \( b \to d + \gamma + g \) the CKM factors \( \lambda_i \) are replaced by \( \zeta_i \equiv V_{tb}^\ast V_{td} \). Now \( \zeta_u, \zeta_c \), and \( \zeta_t \) are all of the same order of magnitude. In the Wolfenstein parametrization [18], one has \( \zeta_i = O(\lambda^2) \), where \( \lambda = \sin \theta_C = 0.22 \). Hence, the corresponding approximation \( \zeta_u = 0 \) cannot be made any longer. The differences due to the inclusion of \( \zeta_u \) to describe the decays \( b \to d + \gamma \) and \( b \to d + g + \gamma \) can be most easily built in the effective hamiltonian framework by modifying the operators \( \hat{O}_1 \) and \( \hat{O}_2 \), encountered in the decay \( b \to s + \gamma \). The dimension-six operator basis again reads as

\[ H_{\text{eff}}(b \to d\gamma) = -\frac{4G_F}{\sqrt{2}} \zeta \sum_{j=1}^8 C_j(\mu) \hat{O}_j(\mu). \quad (17) \]

The operators \( \hat{O}_1 \) and \( \hat{O}_2 \) are defined as
With the operators defined in this basis, the matching conditions, \( C_i(m_W) \), and the corresponding Wilson coefficients at the scale \( \mu, C_i(\mu) \), are precisely the same for the decays \( b \rightarrow d + \gamma \) as given earlier for the \( b \rightarrow s + \gamma \) case. Also, for the decays \( b \rightarrow d + \gamma + g \) only the contributions associated with \( O_2 \) and \( O_7 \) are important. However, in the diagrams associated with \( O_2 \) both \( u \)- and \( c \)-quark propagate in the loop. This is an important difference in comparison to the \( b \rightarrow s + \gamma + g \) case, where there is perfect cancellation in the charm quark and top quark contributions for the loop-momenta below the charm mass threshold. In the decays \( b \rightarrow d + \gamma + g \), this cancellation is upset due to the non-vanishing contribution of the \( u \)-quark, though the contribution from the low momentum region in the loop is numerically small. We shall see later that the long-distance contribution to the FCNC decays \( B \rightarrow X_d \gamma \), modelled after the CC decays given in table 1, is also numerically small, in particular, in the high frequency part of the photon spectrum. We maintain, though we cannot rigorously prove it, that the FCNC decays \( B \rightarrow X_d \gamma \), very much like their dominant counterparts, \( B \rightarrow X_s \gamma \), are also short-distance dominated.

The inclusive branching ratio for \( B \rightarrow X_d \gamma \) depends on \( m_t \) and \( \mu \) through the Wilson coefficients \( C_i(\mu) \), and on the CKM parameters \( \rho \) and \( \eta \) which enter through the CKM factors \( \xi_i \) and \( \xi_c \). In the Wolfenstein parametrization these read as

\[
\xi_i = A\lambda^3(1 - \rho + i\eta), \quad \xi_c = -A\lambda^3.
\]  

This specifies the theoretical framework; we now discuss the inclusive branching ratios for the decays \( B \rightarrow X_s \gamma \) and \( B \rightarrow X_d \gamma \) and their dependence on the various input parameters. The default values of the parameters used in the numerical estimates for the CC and FCNC branching ratios and energy spectra are given in table 2. We shall vary some of these parameters and discuss their effect below. First of all, the masses of the light quarks, \( m_u, m_d \) and \( m_s \), are numerically not important and we fix them to their default values given in table 2. The contribution of the charm quark enters through the loop in the diagrams for the decays \( b \rightarrow (s, d) + \gamma + g \). This dependence is again not very sensitive to the precise value of \( m_c \), but we shall include the effect of its variation in the range \( 1.3 \leq m_c \leq 1.7 \text{ GeV} \). The \( b \)-quark mass in our approach is not a free parameter. Its value is fixed by the \( B \)-hadron mass and the Fermi motion parameter \( p_F \), discussed earlier. The branching ratios for \( B \rightarrow X_s \gamma \) and \( B \rightarrow X_d \gamma \) depend on \( m_t \), though unfortunately not crucially, as will be shown below. We vary \( m_t \) in the presently favoured range from the electroweak phenomenology \( m_t = 140 \pm 40 \text{ GeV} \) [22]. For the scale dependence of the strong coupling constant, which is needed for the estimates of the rates and spectra for the FCNC decays \( B \rightarrow (X_s, X_d) \gamma \), we use the two-loop \( \beta \) function

\[
\alpha_s(\mu) = \frac{12\pi}{(33 - 2N_f) \log(\mu^2/A_s^2)} \times \left(1 - \frac{6(153 - 19N_f) \log \log(\mu^2/A_s^2)}{(33 - 2N_f)^2 \log(\mu^2/A_s^2)}\right). \tag{20}
\]

We set \( N_f = 5 \) and the corresponding \( A_s^{(5)} = 225 \text{ MeV} \), which is the central value from a recent compilation [23]. The dependence of the branching ratio \( BR(B \rightarrow X_s \gamma) \) on \( m_t \) and \( \mu \) is shown in fig. 2, where it is plotted as a function of \( \mu \) with the upper curve corresponding to \( m_t = 180 \text{ GeV} \) and the lower to \( m_t = 100 \text{ GeV} \). Based on this figure, a firm prediction for this branching ratio in the SM is

\[
BR(B \rightarrow X_s \gamma) = (2 - 5) \times 10^{-4}. \tag{21}
\]

This range is somewhat larger than \( BR(B \rightarrow X_s \gamma) = (3 - 4) \times 10^{-4} \), given in ref. [4], as we have now included the dependence of the branching ratio on the scale \( \mu \). As can be seen in fig. 2, the \( m_t \) dependence of \( BR(B \rightarrow X_s \gamma) \) in the assumed \( m_t \)-range is only \( O(25\%) \). It would, therefore, be difficult to extract a meaningful bound on \( m_t \) from a measurement of \( BR(B \rightarrow X_s \gamma) \). We remark that the central value in fig. 2, \( BR(B \rightarrow X_s \gamma) = 3.5 \times 10^{-4} \) (corresponding to \( \mu = 5.0 \text{ GeV} \) and \( m_t = 140 \text{ GeV} \)), is not too far away...
Fig. 2. Inclusive branching ratio \( BR(B \to X_s + \gamma) \) as a function of the renormalization scale \( \mu \), with the upper curve corresponding to \( m_t = 180 \) GeV and the lower to \( m_t = 100 \) GeV. The other parameters used in the analysis are shown in the figure.

from the present (conservative) bound on this branching ratio, namely \( BR(B \to X_s + \gamma) < 9.0 \times 10^{-4} \) (at 90% CL) [6]; hence a measurement in this channel is in the wings!

While confirming the branching ratio in (21) will constitute a non-trivial test of the SM in the flavour sector, one could ask more ambitiously what would be the main thrust of an eventual measurement of \( BR(B \to X_s + \gamma) \)? We maintain, that the overriding theoretical interest in the study of electromagnetic penguins in B-decays lies in the direct measurement of the CKM matrix elements \( |V_{ts}| \) and \( |V_{td}| \) (more precisely \( \rho \) and \( \eta \)). To that end, we show the dependence of the branching ratio \( B \to X_s + \gamma \) on the CKM ratio \((|V_{ts}| / |V_{cb}|)^2\) in fig. 3, where all the other sensitive parameters are varied within the indicated ranges. The unitarity bounds on the ratio of the CKM matrix elements \( 0.25 \leq (|V_{ts}| / |V_{cb}|)^2 \leq 4.0 \) [20] are implicitly included in fig. 3. We remark that, despite considerable uncertainties in the theoretical estimates, a measurement of the inclusive branching ratio for \( B \to X_s + \gamma \) can provide a non-trivial bound on the CKM matrix element \( |V_{ts}| \). For the sake of clarifying the potential strength of an eventual measurement of \( BR(B \to X_s + \gamma) \), we note that a hypothetical value \( BR(B \to X_s + \gamma) = (4 \pm 1) \times 10^{-4} \) would imply \( 0.80 \leq |V_{ts}| / |V_{cb}| \leq 1.60 \), i.e. a determination of \( |V_{ts}| \) to better than a factor 2.

Finally, the decay rates for \( B \to X_d + \gamma \) depend on the CKM parameters \( \rho \) and \( \eta \) which enter through the CKM factors \( \xi_s \) and \( \xi_d \), as already discussed. Numerically, we put \( \lambda = 0.22, A = 0.847 \) (in agreement with the numerical value for \( |V_{cb}| \)) and vary the parameters \( (\rho, \eta) \), in a consistent way to satisfy all the phenomenological constraints from \( x_d, |V_{ub}| / |V_{cb}| = 0.14 \pm 0.05 \) and \( \epsilon_K \), using \( m_t = 140 \pm 40 \) GeV. This gives the following range [5]:

\[
BR(B \to X_d + \gamma) = (0.8-4) \times 10^{-5} .
\] (22)

For \( m_t = 140 \) GeV and \( \mu = 5 \) GeV, this range is somewhat reduced giving \( BR(B \to X_d + \gamma) = (1.0-3.0) \times 10^{-5} \). In the calculation of the photon energy spectrum for \( B \to X_d + \gamma \) shown in fig. 1, we have used the value \( (\rho, \eta) = (0.2, 0.4) \), the central value obtained from the fits of the data for \( m_t = 140 \) GeV in ref. [5].

4. Inclusive photon energy spectrum in \( B \to X + \gamma \)

The inclusive photon energy spectra from the FCNC decays \( B \to X_s + \gamma \) and \( B \to X_d + \gamma \) are shown in fig. 1. Since these spectra were calculated by us in refs. [4,5] with the same approximations and parameter values as used here, we refer to these papers for details. Following observations concerning figs. 1a–1d are in order.
Fig. 3. Inclusive branching ratio $BR(B \to X_s^+ \gamma)$ as a function of the CKM matrix element ratio $(|V_{ts}|/|V_{cb}|)^2$, with the indicated range of the various parameters. Each value of $\mu$ leads to the allowed band, and the three indicated bands correspond to $\mu = \frac{1}{2} m_b$, $m_b$, and $2 m_b$.

The inclusive photon energy spectrum in the decays $B \to X + \gamma$, shown in fig. 1d, divides itself in three regions. The first is the low frequency part $E_\gamma < 1.8$ GeV, which is dominated by the CC decay $B \to X_c + \gamma$, a small intermediate region $1.9 < E_\gamma < 2.1$ GeV, where the CC and FCNC contributions are comparable, and the high frequency part $E_\gamma > 2.1$ GeV, which is dominated by the FCNC radiative decay $B \to X_s + \gamma$. Precise measurements of the photon energy spectra in these regions can therefore be used to test the normalization and shape of the two dominating components. The dip in fig. 1d in the region $E_\gamma = (1.9-2.0)$ GeV has an obvious origin.

The significantly different thresholds in the two CC radiative transitions, due to the presence of a charmed hadron in the decays $B \to X_c + \gamma$ versus non-charmed light hadrons in $B \to X_u + \gamma$, result in the longer $E_\gamma$-tail for the latter. However, in the region where the photons from the dominant CC process $B \to X_c + \gamma$ range out (say above 2 GeV in the $B$ rest frame), the inclusive photon spectrum is dominated by the CKM allowed FCNC radiative decay $B \to X_s + \gamma$.

The separation of the high frequency part of the spectrum in the two FCNC components $B \to X_s + \gamma$ and $B \to X_d + \gamma$ would require flavour tagging the hadrons recoiling against the photon, for example, by demanding the overall strangeness quantum number of $X_s$ being 0 and $X_d$ being equal to $\pm 1$. At the exclusive level, this can be exemplified by the decays $B \to K^* + (n\pi) + \gamma$ versus $B \to \rho + (n\pi) + \gamma$.

Our calculations also indicate that the long distance (i.e. CC) contamination to the short distance piece (i.e. penguin dominated FCNC decays) is small in the high energy region of the photon spectrum. This is a rather important conclusion, since otherwise the final states in the CC radiative decays $B \to X_u + \gamma$ and the FCNC decays $B \to X_d + \gamma$ very easily mock up each other.

This analysis also demonstrates that probably the most difficult to measure is the CC component $B \to X_u + \gamma$, since there is no region in which it dominates. The only way to isolate this component is probably through the measurement of the photon spectrum in the low frequency part and demanding the absence of charmed hadrons in $B \to X + \gamma$, recoiling against the photon. With a vertex detector, perhaps this is feasible in a limited range of photon energy, though the non-B-background will be formidable, perhaps prohibitive.

Finally, one could use the inclusive photon energy spectrum in $B \to X_i + \gamma$, given in fig. 1, combined with the assumption of $K^*$-dominance of the hadron mass spectrum in the limited kinematic domain $(m_K + m_\pi) \lesssim m_X \lesssim 1.0$ GeV to estimate the exclusive branching ratio $BR(B \to K^* + \gamma)$, as was done in ref.
Since one of the new ingredients of the present analysis is the dependence of the branching ratios on the renormalization scale, we show this dependence for $\text{BR}(B \rightarrow K^* + \gamma)$ in fig. 4. The three curves correspond to $p_F = 0.21$ GeV (top), $p_F = 0.30$ GeV (central), and $p_F = 0.39$ GeV (bottom), and the other parameters are given in table 2. This gives the following prediction:

$$\text{BR}(B \rightarrow K^* + \gamma) = (3-8) \times 10^{-5},$$  \hspace{1cm} (23)

to be compared with the present experimental bound [6]: $\text{BR}(B \rightarrow K^* + \gamma) < 9.0 \times 10^{-5}$ (at 90% CL). This mode therefore should be seen soon, though the interpretation of the data in this case is model dependent. This, in our model, is exemplified by the $p_F$-dependence of $\text{BR}(B \rightarrow K^* + \gamma)$ shown through the three curves in fig. 4. We recall that the inclusive branching ratios for $B \rightarrow X_s + \gamma$ and $B \rightarrow X_s + \gamma$ do not depend on $p_F$ (more generally on the wave function model) and hence are more predictive.

The measurement of the inclusive photon energy spectrum in $B$-decays would be a benchmark measurement opening up new experimental opportunities using prompt photons in heavy quark weak decays. We hope that the calculations presented here are useful in the interpretation of data on radiative $B$-decays, in particular concerning the electromagnetic penguins.
