The time-dependent Schrödinger equation (TDSE) is usually treated in the real space in the textbook. However, it makes the numerical simulations of strong-field processes difficult due to the wide dispersion and fast oscillation of the electron wave packets under the interaction of intense laser fields. Here we demonstrate that the TDSE can be efficiently solved in the momentum space. The high-order harmonic generation and above-threshold ionization spectra obtained by numerical solutions of TDSE in momentum space agree well with previous studies in real space, but significantly reducing the computation cost.

Keywords: high-order harmonic generation, above-threshold ionization, numerical method

DOI: 10.1088/1674-1056/ab6553

1. Introduction

Strong-field physics has attracted a lot of attention in the last three decades. The nonperturbative phenomena, such as high-order harmonic generation (HHG), above-threshold ionization (ATI), double ionization (DI), above-threshold dissociation (ATD), *etc.*, have been well studied.^[1,2] For the non-linear dynamic processes, there are seldom analytic solutions. Most of the theoretical works are based on numerical simulations of the time-dependent Schrödinger equation (TDSE).^[3] After obtaining the wavefunction at arbitrary times, all the experimental observables can be extracted from it. However, it is not an easy task to calculate the time-dependent wavefunction precisely. The ionized wavepacket may be pushed very far away from the parent ion in the real space. In addition, the kinetic energy of the photoelectron may be up to $10U_p$ (U_p is the ponderomotive energy.) after rescattering from the core.^[1,2,4,5] For example, if the laser intensity $I = 1 \times 10^{14}$ W/cm², wavelength $\lambda = 800$ nm, the full width at half maximum (FWHM) of the pulse $\sigma = 30$ fs, the radial box in real space should be $R_{\max} = 2617$ a.u. to include the backscattering electrons. The density of the grids should be very high to accurately describe the fast oscillation of the high-energy wavefunction.^[6] At least, ten thousand grids should be used. This is very time consuming during the evolution of the wavefunction, and the memory of the computer system should be big enough. To overcome this problem, parallel computing methods in real space have to be developed. Alternatively, a hybrid wavefunction splitting algorithm has been proposed.^[7]

In this scheme, the wavefunction near the atomic core is calculated in the real space. The external wavefunction is transformed into the momentum space by neglecting the long-range Coulomb potential to reduce the computation cost. In the split-operator method, the wavefunction is also transformed in different spaces by using FFT in every time step.^[8] In this work, different from previous schemes, we treat the whole TDSE and wavefunction directly in the momentum space,^[9] which can greatly reduce the cost of the numerical computations since both the bound and the continuum states are localized functions of the momentum p . The idea is similar to the treatment of period solids. They also have some differences. For periodic solids, the problem is transformed to the crystal momentum space based on the Bloch theorem, rather than the electron momentum space. The equations in one unit cell can be further treated in the momentum space by our method.

To our knowledge, this is the first work solving the strong-field problems of gases in the momentum space. The paper is organized as follows. We introduce the details of the numerical methods for solving TDSE in both real and momentum spaces in Section 2. The results and discussions of HHG and ATI spectra are presented in Section 3. We summarize our findings in Section 4.

2. Theoretical methods

For simplicity, in this work we take the one-dimensional TDSE as an example to compare its solution in real and momentum spaces, respectively. Atomic units (a.u.) are used

2.1. TDSE in real space

The TDSE with laser-atom interaction in the dipole approximation in the real space is written as

$$i \frac{\partial \Psi(x, t)}{\partial t} = \left[-\frac{d^2}{2dx^2} + V(x) + xE(t) \right] \Psi(x, t). \quad (1)$$

We use a model potential^[10] $V(x) = -1/\sqrt{1+x^2}$ to represent the symmetric atomic system. The electric field of the laser pulse is obtained by

$$E(t) = -\frac{dA(t)}{dt}, \quad (2)$$

where $A(t)$ is the laser vector potential. In this work, its form is

$$A(t) = \frac{E_0}{\omega} \sin^2 \left(\frac{t\pi}{\tau} \right) \cos(\omega t),$$

where E_0 is the field strength, ω is the angular frequency, and τ is the total pulse duration.

There are many numerical methods for solving the eigenstates of the field-free system, such as B -spine basis expansion,^[3,10,11] spacial grid discretization,^[8,12,13] and so on. For the time evolution, there are Crank–Nicholson method,^[3] split-operator method,^[8,12] Arnoldi/Lanczos method,^[6,14] and so forth. After obtaining the time-dependent wavefunction, the HHG spectra can be calculated by the Fourier transform of the laser-induced dipole in the length, velocity, and acceleration forms, respectively.^[15,16] The box boundary x_{\max} should be bigger than $2E_0/\omega^2$ to include all the electrons being able to return to the parent ion at $x = 0$ to emit high harmonics. Absorbing functions are utilized to avoid reflection from the boundary. For ATI, the boundary x_{\max} must be bigger than $\sqrt{20U_p}\tau$ to include all the rescattered electrons as discussed in Section 1. Otherwise, the information of high energy electrons will be lost by the absorbing function. The ATI spectra can be calculated from the final wavefunction after laser pulses by the energy window operator,^[17,18] surface flux,^[12] or projecting on the plane waves,^[19] scattering states,^[10] Coulomb waves,^[6,19] and so on. Since there have been many studies, here we will not give the details.

2.2. TDSE in momentum space

The TDSE in the momentum space^[9] can be obtained by Fourier transform of Eq. (1)

$$i \frac{\partial \Psi(p, t)}{\partial t} = \left\{ \frac{[p + A(t)]^2}{2} + \int_{-\infty}^{+\infty} \frac{V'(p-p')}{\sqrt{2\pi}} dp' \right\} \Psi(p, t). \quad (3)$$

In this case, the term $V'(p)$ is the Fourier transform of the Coulomb potential $V(x)$.

The eigenstates wavefunctions $|\psi_n(p)\rangle$ and eigenvalues E_n are obtained by direct diagonalization of the field-free Hamiltonian matrix

$$H_{i,j}^0 = \frac{p_i^2}{2} \delta_{ij} + \frac{dp}{\sqrt{2\pi}} V'(p_i - p_j). \quad (4)$$

To calculate the time evolution of the wavefunction in Eq. (3), we adopt the split-operator method in the following form

$$\begin{aligned} \Psi(p, t + \Delta t) = & \exp \left(-iH^0 \frac{\Delta t}{2} \right) \exp \left(-iH^1 \left(t + \frac{\Delta t}{2} \right) \Delta t \right) \\ & \times \exp \left(-iH^0 \frac{\Delta t}{2} \right) \Psi(p, t) + O(\Delta t^3), \end{aligned}$$

where the laser-atom interaction term $H^1(t) = pA(t) + A^2(t)/2$. The evolution operator $\exp(-iH^0 \Delta t/2)$ is expanded by

$$\sum_n \exp(-i\Delta t E_n/2) |\psi_n(p)\rangle \langle \psi_n(p)|$$

in its eigenstate space.^[20] This expansion is only calculated once before the time evolution. The evolution operator $\exp(-iH^1 \Delta t)$ can be directly applied to the wavefunction $\Psi(p, t)$ in the momentum space. So the time-evolution process is very efficient.

After obtaining the wavefunction at arbitrary times, the transition dipole in the velocity form is

$$d_v(t) = \int_{-P_{\max}}^{+P_{\max}} \Psi^*(p, t) (\hat{p} + A(t)) \Psi(p, t) dp. \quad (5)$$

The HHG spectra are obtained by Fourier transform of $d_v(t)$

$$F(\Omega) = \left| \int_0^\tau d_v(t) \exp(-i\Omega t) dt \right|^2. \quad (6)$$

To obtain the ATI spectra, we have to project out the bound states of system,

$$|\Psi'(p, \tau)\rangle = |\Psi(p, \tau)\rangle - \sum_{n=1}^{nb} \alpha_n |\psi_n(p)\rangle, \quad (7)$$

where $\alpha_n = \langle \psi_n(p) | \Psi(p, \tau) \rangle$ is the coefficient of the bound states, nb is the number of field-free bound states $|\psi_n(p)\rangle$. It is different from the cases in the real space, where the bound wave and ionized wave can be separated in space by additional evolution of TDSE without laser fields. However, in the momentum space, they cannot be automatically separated. We have to project them out.

The momentum distribution of the photoelectron is the direct square of $|\Psi'(p, \tau)\rangle$. The $+p$ wave and $-p$ wave correspond to the same ATI energy $E_e = p^2/2$. The ATI yield on the detector is the addition of the corresponding probability of

wavefunction in the momentum space, which can be directly calculated by

$$Y(E_c = p^2/2) = |\Psi'(p_-, \tau)|^2 + |\Psi'(p_+, \tau)|^2. \quad (8)$$

There is no need to deal with the final wavefunction by different complex methods used for the case in real space as mentioned in the above subsection.

3. Results and discussion

In this section, we compare the eigenstates of the system and the HHG and ATI spectra calculated in different spaces.

3.1. Eigenstate of the system

For the field-free Hamiltonian in the momentum space in Eq. (4), the ground state can also be obtained by imaginary time propagation (ITP)^[3] by changing $t \rightarrow -it$. The converged ground state energy is $E_1 = -0.669775$ a.u., agreeing well with the results by the ITP of Eq. (1) in the real space. We show the ground state $\psi_1(x)$ in the real space in Fig. 1(a). The direct Fourier transform of $\psi_1(x)$ and the ground state $\psi_1(p)$ in momentum space obtained by ITP of Eq. (3) are illustrated in Fig. 1(b). One may find that they are in accord with each other. The distribution of the wavefunction in real space is around twice wider than that in momentum space. For a continuum state, the wavefunction oscillates in the whole real space, while the wavefunction is only a very narrow localized point in the momentum space. As a result, one may predict that the computation cost will be much smaller in the momentum space.

Fig. 1. Wavefunction of the ground state in the real space (a) and momentum space (b). The wavefunctions are normalized in the real space and momentum space, respectively. The direct Fourier transform of $\psi_1(x)$ in panel (a) is plotted by solid black line in panel (b).

3.2. HHG and ATI spectra

In this subsection, we calculate the HHG and ATI spectra of the model atomic system. The laser intensity we used is $I = 1 \times 10^{14}$ W/cm². The wavelength $\lambda = 800$ nm, the total pulse duration $\tau = 10$ optical cycles. The HHG spectra calculated by the laser-induced dipole in the velocity form by solving the TDSE in the real space and momentum space are presented in Fig. 2. For clarity, we shift the red-dotted line down

by three orders. One may find that the results are almost the same. In our simulations, the convergence has been checked. The range of p is $[-3, 3]$ a.u., $dp = 0.01$ a.u., and the time step $dt = 0.1$ a.u. The calculated cutoff energy agrees well with the law by the classical three-step model $I_p + 3.17U_p = 24\omega$, with $U_p = E_0^2/4\omega^2$.^[1]

Fig. 2. Comparison of HHG spectra obtained by TDSE in the real and momentum spaces, respectively. For clarity, the red-dotted line is down shifted by three orders. The laser parameters can be found in the text.

Fig. 3. Comparison of ATI spectral calculated by TDSE in the real and momentum spaces, respectively. The red dotted line is down shifted by two orders for clarity. The laser parameters are the same as those in Fig. 2.

For the ATI spectra, it contains two main parts. One is the direct ionization electrons. Their maximum energy is around $2U_p$ from the classical Newton equation. The other part is the rescattering electrons whose cutoff energy is around $10U_p$ when the electron is backward rescattered. It is very hard to obtain the converged results in real space TDSE, especially near the $10U_p$ cutoff. We use the method in Ref. [7] to treat the wavefunction by splitting algorithm to calibrate our results. The inner wavefunction is calculated by Eq. (1) in the real space, the outer wavefunction is calculated in the momentum space by neglecting the Coulomb potential. We compare the ATI spectra by the splitting algorithm and the direct evolution of TDSE in Eq. (3) in the momentum space in Fig. 3. One may find that the results agree well with each other. The positions of $2U_p$ and $10U_p$ cutoff energies are in accord with the predictions by classical simulations. In our calculations, the box in p space is in a very small range of $[-4, 4]$ a.u., no matter how long the laser pulse is. For TDSE in real space, the box in the x space is at least hundreds times larger to effectively retrieve the

ATI yield in femtosecond pulses. Longer pulses will further increase the box size and computation cost significantly in the real space. The resolution of energy is $dE = p dp$. For $10U_p$ electrons, the density of p grids we used is $dp = 0.0033$ a.u., which is around one order higher than that of x grids. However, the total computation cost is still much lower in the momentum space even for a few-cycle short pulse.

4. Conclusions

In summary, we studied the eigenstates of the atomic Hamiltonian system in the momentum space. Both the bound and continuum states are localized waves in the momentum representation. We also solved the TDSE in the momentum space to simulate the strong-field HHG and ATI processes. Details of one-dimensional calculations are illustrated. Good agreement has been achieved compared to the cases of the real space. However, it reduces the computation cost greatly. It also provides us a new view of the strong-field processes in the momentum space. We will extend it to molecular systems and higher dimensions in our future work. For the three-dimensional (3D) TDSE in the spherical coordinates, it could be decomposed by the radial part and angular part with spherical harmonics in the momentum space. The range of the radial part in the momentum space should be small and reduce com-

putation costs. In addition, it has been demonstrated that the velocity gauge is better than the length gauge in the simulation of ATI in the real space by requiring a small number of spherical harmonics. Thus the 3D TDSE in the momentum space is expected to be efficient in the same way.
