Abstract

We present multiwavelength studies of a transient X-ray source, XMMSL1 J131952.3+225958, associated with the galaxy NGC 5092 at $z = 0.023$ detected in the *XMM-Newton* SLew survey (XMMSL). The source brightened in the 0.2–2 keV band by a factor of >20 in 2005 as compared with previous flux limits and then faded by a factor of >200 as observed with *XMM-Newton* in 2013 and with *Swift* in 2018. At the flaring state the X-ray spectrum can be modeled with a blackbody at a temperature of ~ 60 eV and an overall luminosity of $\sim 1.5 \times 10^{43}$ erg s^{-1}. A UV flare and optical flare were also detected with the *Galaxy Evolution Explorer* and the Sloan Digital Sky Survey, respectively, within several months of the X-ray flare, whose nonstellar UV–optical spectrum can be described with a blackbody at a temperature of $\sim(1-2) \times 10^{4}$ K and a luminosity of $\sim(2-6) \times 10^{43}$ erg s^{-1}. Interestingly, mid-infrared monitoring observations of NGC 5092 with the *Wide-field Infrared Survey Explorer* 5–13 yr later show a continuous flux decline. These dramatic variability properties, from the X-ray through UV and optical to infrared, appear to be orderly, suggestive of a stellar tidal disruption event (TDE) by a massive black hole, confirming the postulation by Kanner et al. This TDE candidate belongs to a rare sample with contemporaneous bright emission detected in the X-ray, UV, and optical, which are later echoed by dust-reprocessed light in the mid-infrared. The black hole has a mass of $\sim 5 \times 10^{7}\,M_{\odot}$, residing in a galaxy that is dominated by a middle-aged stellar population of 2.5 Gyr.

Unified Astronomy Thesaurus concepts: Tidal disruption (1696); Galaxy nuclei (609)

1. Introduction

A tidal disruption event (TDE) occurs when a star passes so close to a supermassive black hole (SMBH) at the center of a galaxy that the tidal force of the SMBH is able to overcome the self-gravity of the star and disrupt it. During this process, roughly half of the stellar material is accreted onto the SMBH, resulting in a flare of radiation peaking in soft X-ray and UV band, fading away on timescales of months to years (Rees 1988). These events are a unique probe of quiescent SMBHs at the center of normal galaxies, which are otherwise difficult to detect and may contribute to the growth and evolution of SMBHs. Meanwhile, TDEs are an ideal laboratory for studying the accretion around SMBHs, as we may witness the whole process where the accretion rate varies from low to super-Eddington, which normally takes millennia or more in active galactic nuclei (AGNs; e.g., Komossa 2015). In TDEs, since the debris of the stars are accreted to the BHs from a close distance, the compact TDE disks will emit mostly X-rays. The first TDE was detected in soft X-ray in the [H II]-like nucleus of NGC 5905 (Bade et al. 1996; Komossa & Bade 1999). The X-ray luminosity showed a variability amplitude larger than a factor of 150 within 2 yr, with an extremely soft X-ray spectrum in the high state (photon index $\Gamma \sim 4$). All these properties are consistent with the expectations of the TDE model. So far, only about two dozen TDEs have been discovered by the detection of their X-ray flares (e.g., Komossa & Greiner 1999; Esquej et al. 2008; Lin et al. 2011; Saxton et al. 2012, 2017, 2019; refer to Komossa 2015 for a recent review). The observed X-ray light curves of TDEs typically follow a power-law decline approximately by $t^{-5/3}$ over timescales of months to years, roughly consistent with the theoretical prediction (e.g., Rees 1988). Their X-ray spectra are mostly very soft, with power-law photon index $\Gamma \sim 4$–5, and can be described with blackbody emission with a temperature around 40–100 eV (corresponding to $\sim 10^{5}$–10^{6} K; Komossa 2002). There is also a class of transients that shows luminous and energetic flaring in hard X-ray and γ-ray bands accompanied by radio emission. Here, the rapid variability, huge X-ray peak luminosity, blazar-like spectral energy distribution (SED), and optically inactive host galaxy can all be explained by the launch of a relativistic jet following the tidal disruption of a star. TDEs with jets could provide new insight into the formation and launch of radio jets (e.g., Bloom et al. 2011; Burrows et al. 2011; Levan et al. 2011; Zauderer et al. 2011; Cenko et al. 2012; Brown et al. 2015).

In recent years, thanks to the development of high-cadence optical and UV surveys, a number of TDEs have been found as optical and UV transients on timescales of months to years (Gezari et al. 2006, 2008, 2012; Holoien et al. 2014, 2019;

Hung et al. 2017; van Velzen et al. 2019; see van Velzen 2018 for a recent compilation). The optical and UV SED can normally be fitted with blackbody radiation at temperatures $\sim(1$–$3) \times 10^4$ K (van Velzen 2018). The origin of the optical and UV emission in TDEs is unclear yet, as the peak temperature is much lower than that expected from the canonical TDE models (e.g., 10^5–10^6 K). Current models for the optical emission mainly include (1) thermal emission from a disk (Lodato & Rossi 2011); (2) emission during the formation of the accretion disk, in which the emission is powered by shocks from intersecting stellar debris streams (Piran et al. 2015); and (3) reprocessing of the hotter disk emission by the outer envelope, where the envelope is formed by outflow during the accretion process (Guillochon et al. 2014; Metzger & Stone 2016) or stellar debris (Loeb & Ulmer 1997). Only a few TDEs have contemporaneous X-ray and optical detections, e.g., ASASSN-14li (Miller et al. 2015; Cenko et al. 2016; Holoien et al. 2016), XMMSL1 J074008.2−853927 (Saxton et al. 2017), AT2018fyk (Wevers et al. 2019), AT2018zr (van Velzen et al. 2019), and ASASSN-19bt (Holoien et al. 2019). A unified, viewing-angle-dependent model has been proposed by Dai et al. (2018) for interpreting the various classes of observed TDEs. In this model, the X-ray emission, originating from the inner disk, would be obscured by the optically thick super-Eddington disk wind when viewed close to the disk plane, and optical TDEs are produced by the reprocessing of the X-ray photons. When viewing high above the disk, where the gas is optically thin to absorption, one would expect to see both the X-ray and optical/UV emission. The detection of strong Bowen fluorescence lines in the optical spectrum of several TDEs with X-ray nondetections supports this scenario (Leloudas et al. 2019).

TDEs in gas-rich environments may illuminate circumnuclear material, and the reprocessed emission lines provide us valuable information for the study of the cores of quiescent galaxies (e.g., Komossa et al. 2008; Wang et al. 2011, 2012). If the TDE takes place in a dusty environment, most of the UV/optical photons will be absorbed by dust grains in the vicinity of the BH and reradiated in infrared (IR), which is the IR echo of TDE (Komossa et al. 2009; Dou et al. 2016, 2017; Jiang et al. 2016, 2017; Lu et al. 2016; van Velzen et al. 2016; Wang et al. 2018). The TDE research is currently hampered by the small number of known events. Many questions remain, including the event rate and luminosity function of TDEs, the origin of the diversity of two classes of TDEs, how the jets form, the relation of the TDE incidence to the host galaxy, and the star-forming history. To answer these questions, a large number of TDEs are needed, especially those showing X-ray flares.

The *XMM-Newton* SLew survey (XMMSL; Saxton et al. 2008) contains data taken with the EPIC-pn camera during slews from one pointed observation to another. In the second XMMSL catalog (XMMSL2),[9] 84% of the sky has been covered with a flux limit of 6×10^{-13} erg s^{-1} cm^{-2} and a mean exposure time of 6 s in the energy band of 0.2–2 keV. Comparison of source fluxes in the XMMSL survey with those measured in the previous *ROSAT* All-Sky Survey (RASS; Voges et al. 1999) performed in the 1990s has allowed the detection of five sources that are suggested to be TDEs: XMMSL1 J1115+1806 (Esquej et al. 2008), XMMSL1 J1323

+4827 (Esquej et al. 2008), XMMSL1 J1201+3003 (Saxton et al. 2012), XMMSL1 J0740-8539 (Saxton et al. 2017), and XMMSL2 J1446+6857 (Saxton et al. 2019). All five of these TDEs show soft X-ray flux variations greater than a factor of 50 in optically inactive galaxies. For three (XMMSL1 J1115 +1806, XMMSL1 J1323+4827, XMMSL J1201+3003) of these five TDEs, the outburst X-ray spectra are very soft, with photon index $\Gamma \sim 3$–4 if fitted with a single power law. TDE XMMSL1 J0740–8539 shows both a thermal and a nonthermal component with a spectrum that may be modeled with thermal emission in the UV band, a power law with $\Gamma \sim 2$ dominating in the X-ray band above 2 keV, and a soft X-ray excess with an effective temperature of ~ 86 eV. XMMSL2 J1446+6857 has flat X-ray flux for ~ 100 days and then falls by a factor of 100 over the following 500 days. Throughout the evolution of the event, the X-ray spectrum can be modeled with a power law of $\Gamma \sim 2.6$ and may be solely due to Compton upscattering of thermal photons from the disk.

In this paper, we present the multiwavelength studies of a TDE candidate, XMMSL1 J131952.3+225958 (hereafter XMMSL1 J1319+2259), associated with the galaxy NGC 5092 at a redshift of $z = 0.023$. The X-ray source was first detected in the XMMSL survey in 2005. It was noted as a possible TDE candidate in a sample study of X-ray transients selected from the XMMSL by Kanner et al. (2013), based on variability by a factor of >10 compared to the previous RASS upper limit, though there was a lack of further compelling evidence. Its X-ray flux was found to be ~ 240 times fainter in a pointed observation with *XMM-Newton* in 2013. The Sloan Digital Sky Survey (SDSS; York et al. 2000) and *Galaxy Evolution Explorer* (*GALEX*; Morrissey et al. 2005; Martin et al. 2005) observations in 2005 show that there was also an optical and UV flare in the nucleus of NGC 5092. This galaxy showed a continuous decline of the *Wide-field Infrared Survey Explorer* (*WISE*; Wright et al. 2010) infrared flux from 2010 to 2018, suggesting an infrared echo following the optical/UV/X-ray flare.

In Section 2, we describe the X-ray observations, data reduction, and analysis of XMMSL1 J1319+2259. In Section 3, we compile and study the multiwavelength observations, from IR to UV, of the nuclear and host galaxy of this source, and an optical spectral analysis is performed in Section 4. The results are summarized and discussed in Section 5. Details of the data reduction and analysis are described in the Appendix.

Throughout this paper, we adopt a flat cosmology with $H_0 = 70$ km s^{-1} Mpc^{-1}, $\Omega_m = 0.3$, and $\Omega_\Lambda = 0.7$. The redshift of NGC 5092 ($z = 0.023$) corresponds to a luminosity distance of 100.2 Mpc.

2. X-Ray Data Analysis

2.1. The X-Ray Source XMMSL1 J1319+2259 and X-Ray Observations

The source XMMSL1 J1319+2259 was first detected in the soft X-ray band (0.2–2 keV) on 2005 July 15 during an XMM slew observation, with an exposure time of 4.6 s. The source position, taken from the XMMSL2 catalog, is at R.A. = $13^h 19^m 52^s.2$, decl. = $22°59'58''.2$ (J2000), with a position error of $8''$ in radius at the 68% confidence level (Saxton et al. 2008). Within this error circle, there is only one cataloged bright source (see Figure 1), the galaxy NGC 5092,

Figure 1. An *r*-filter image of the galaxy NGC 5092 from the SDSS, taken on 2005 April 2, with the center of the galaxy marked with a white cross. Also shown is the *XMM-Newton* slew error circle (red; $8''$ at the 68% confidence level) and *XMM-Newton* pointed error circle (green; $1''.9$ at the 68% confidence level).

2018 Aug 24	03106172001	*Swift*/XRT	576	0.2–2	<0.005	<1.40

Note. The unabsorbed fluxes with 1σ error and 2σ upper limits are estimated using XSPEC as described in Section 2.1.1.

at R.A. = $13^h19^m51^s.5$, decl. = $22°59'59''.6$ (Gaia Collaboration 2018), with a redshift of 0.023. By analyzing the XMMSL data, we find that the source is detected only in the 0.2–2 keV soft X-ray band with a count rate of 3.0 ± 0.8 counts s^{-1} and has a 2σ upper limit of 1.0 counts s^{-1} in the 2–10 keV band, indicative of a soft X-ray spectrum. There was another slew coverage of NGC 5092 in 2002 with an exposure time of 10 s, setting an upper limit count rate of 0.4 counts s^{-1} (<5.2×10^{-13} erg s^{-1} cm^{-2}; see Section 2.1.1) in the 0.2–2 keV band. The galaxy NGC 5092 was not detected in the RASS in 1990 July, which yields an upper limit of 0.04 counts s^{-1} in the 0.2–2 keV band, or 3.5×10^{-13} erg s^{-1} cm^{-2} in flux (Section 2.1.1). This sets a stringent upper limit on the X-ray luminosity of 4.2×10^{41} erg s^{-1}, indicating that NGC 5092 does not host a strong AGN. An *XMM-Newton* pointed observation with an exposure of ~8600 s was carried out on 2013 December 21 (PI: Richard Mushotzky; ObsID = 0721830301). We perform data reduction following the standard procedures with the software *XMM-Newton* Science

Analysis System (SAS version 16.0.0; Gabriel et al. 2004), and the details are described in Appendix A.1. The refined source position given in 3XMM-DR8 (Rosen et al. 2016) is R.A. = $13^h19^m51^s.6$, decl. = $22°59'58''.8$, with a source position error of $1''.9$ at the 68% confidence level (shown as a green circle in Figure 1). Detailed observational information of the three detectors (pn, MOS1, and MOS2), including the good exposure time and count rates, is summarized in Table 1.

There was also an observation performed by the X-ray Telescope (XRT; Burrows et al. 2005) on board the Neil-Gehrels *Swift* Observatory (Gehrels et al. 2004) in 2018 August with an exposure time of 576 s, setting a 2σ upper limit of 0.005 counts s^{-1}, or 1.6×10^{-13} erg s^{-1} cm^{-2} assuming a power-law spectral model with $\Gamma = 2.1$ modified by Galactic absorption (see Section 2.1.1). Table 1 summarizes the information of all the available X-ray observations of this source and its detection. Among the five observations, the source was detected in two, namely, the XMMSL in 2005 and the pointed XMM observation in 2013.

Table 2
Spectral Fitting to the XMMSL and XMM Pointed Observation of XMMSL1
J1319+2259

Obs	Model	Γ	kT (eV)	C (dof)
pointed	tbabs*(zpo)	$2.1^{+0.5}_{-0.5}$	$(-)$	17.5(33)
slew	tbabs*(zpo)	$4.4^{+2.0}_{-1.7}$	$(-)$	8.9(11)
"	tbabs*(zbb)	$(-)$	$64.2^{+31.2}_{-22.0}$	9.2(11)
"	tbabs*(zpo+zbb)	2.1(fixed)	$64.0^{+31.2}_{-22.1}$	9.2(11)

Note. All fits include absorption by Galactic column (model tbabs, $N_H = 1.22 \times 10^{20}$ atoms cm^{-2}, abundances from Wilms et al. 2000). For the XMMSL spectrum, while fitted with model tbabs*(zpo+zbb), parameters of the power-law model are fixed at values from XMM pointed spectrum fitting. Errors are at 90% confidence level.

2.1.1. X-Ray Spectral Analysis

Here we perform spectral analysis for the XMMSL and XMM pointed observation using XSPEC (version 12.9.1; Arnaud 1996). We extract photons detected in the range of 0.2–10 keV, where the data are best calibrated and are in the most sensitive range for *XMM-Newton* EPIC cameras. For the XMM pointed observation, the MOS1 and MOS2 spectra are combined, taking into account the responses, background, and ancillary files. The combined MOS and the pn spectrum are jointly fitted in all the analyses below. Given the small number of photons of the detections, the combined MOS spectrum is binned with a minimum of three counts per bin, the pn spectra in the XMMSL and XMM pointed observation are binned to have only one photon per group in 0.2–10 keV, and the C-statistic is used for the fitting. The Galactic equivalent N_H column density toward NGC 5092 is 1.22×10^{20} cm^{-2} (Willingale et al. 2013), which is always taken into account and modeled by tbabs with the element abundances set to those in Wilms et al. (2000). We find that in all the spectral fits below, no additional absorption, neutral or ionized, is required. The fitting results are summarized in Table 2. Note that the quoted uncertainties of the fitted parameters are at the 90% confidence range.

For the XMM pointed observation, a power law modified by Galactic absorption, tbabs×zpowerlaw, provides an acceptable fit to the pn+MOS spectrum with a photon index $\Gamma = 2.1^{+0.5}_{-0.5}$. The corresponding unabsorbed (corrected for Galactic absorption) 0.2–2 keV flux is $0.3^{+0.1}_{-0.1} \times 10^{-13}$ erg s^{-1} cm^{-2}, with a rest-frame luminosity of $3.6^{+1.2}_{-1.2} \times 10^{40}$ erg s^{-1}. The Eddington ratio $L_{0.2-2\,keV}/L_{Edd}$ is estimated to be $\sim 5.7 \times 10^{-6}$ ($M_{BH} = 5.0^{+5.6}_{-2.9} \times 10^{7} M_{\odot}$; please refer to Section 4 for the BH mass estimation). We note that this value should be an upper limit, as the emission from the host galaxy may significantly contribute to the detected flux at such a low luminosity level.

For the pn spectrum taken in the XMMSL observation, which is very soft, we first try two simple models of the source emission: a power law (zpowerlaw) and a blackbody (zblackbody). The blackbody model provides a good fit to the data, yielding a temperature of $kT = 64.2^{+31.2}_{-22.0}$ eV, which is consistent with measurements from previous TDEs (e.g., Komossa 2002). In the rest-frame 0.2–2 keV band, the unabsorbed flux is $70.9^{+29.8}_{-22.4} \times 10^{-13}$ erg s^{-1} cm^{-2}, corresponding to a luminosity of $8.6^{+3.6}_{-2.7} \times 10^{42}$ erg s^{-1} and thus an Eddington ratio $L_{0.2-2\,keV}/L_{Edd} \sim 1.4 \times 10^{-3}$. The overall luminosity of the blackbody emission is $\sim 1.5 \times 10^{43}$ erg s^{-1}

($L_{0.01-100\,keV}/L_{Edd} \sim 2.4 \times 10^{-3}$). A power-law model also gives an equally good fit with $\Gamma = 4.4^{+2.0}_{-1.7}$. We also try to fit the spectrum with a blackbody plus a power-law model, but we find that the addition of a power-law component does not improve the fit. Figure 2 shows the two X-ray spectra and model fits. The spectrum became harder from 2005 to 2013, and the flux dropped by a factor of $\sim$240.

For the nondetections in the remaining observations, the flux limits are estimated (see Table 1) by assuming the source spectra to be the same as those found in the XMM pointed observation, since the source appeared to be at a low state in all these observations.

2.1.2. X-Ray Light Curve

The obtained unabsorbed 0.2–2 keV fluxes and upper limits are plotted in Figure 3. The flux increased by a factor of more than 20 in 2005 compared to the RASS observation and then dropped by a factor of $\sim$240 from 2005 to 2013 as observed in the XMM pointed observation, remaining in a low state until the *Swift* observation in 2018. Though the data points are scarce, such a large-amplitude X-ray flare resembles those of the known X-ray-selected TDEs (see Komossa 2015 for review). In the process of tidal disruption, the X-ray flare is ignited when the most bound material returns to the pericenter after completing one orbit. Assuming that the material is uniformly distributed in the disrupted stellar debris, as demonstrated by numerical simulations, the mass fallback rate after one post-disruption orbit is

$$\dot{M} \propto \left[\frac{t - t_0}{1 \text{ yr.}} \right]^{-5/3}, \tag{1}$$

where t_0 is the time at which the disruption process occurs (Evans & Kochanek 1989; Ayal et al. 2000). The X-ray radiation power is assumed to evolve following this $t^{-5/3}$ law. Assuming that this is a TDE and the debris evolution follows the above fallback model, the luminosity declines following the canonical $t^{-5/3}$ law

$$L(t) = L_{1\,yr} \times \left[\frac{t - t_0}{1 \text{ yr}} \right]^{-5/3} \text{ erg s}^{-1}, \tag{2}$$

where $L_{1\,yr}$ is the luminosity 1 yr after the disruption occurring at t_0. The two parameters, $L_{1\,yr}$ and t_0, can be determined by using the two detected data points (luminosities), giving $L_{1\,yr} = (1.3 \pm 0.5) \times 10^{42}$ erg s^{-1} and $t_0 = 2005.2 \pm 0.1$, i.e., the disruption time is somewhere around 2005 February to April. Assuming that the flux begins to decrease at an epoch from about 1 to 3 months after the disruption,[10] the derived peak luminosity in 0.2–2 keV is in the range of $\sim(1-7) \times 10^{43}$ erg s^{-1}. We note that the X-ray properties of this variable source, the amplitude of the flare, the very soft spectral shape, and the peak luminosity are typical of the TDEs known so far.

3. Optical, UV, and Infrared Data Analysis

The galaxy NGC 5092 was covered in several surveys, e.g., the All-sky Imaging Survey (AIS) conducted by *GALEX* in

---

[10] This has been observed to be the case for TDEs detected in the optical/UV band (Stone et al. 2013; van Velzen et al. 2019), and we assume that the X-ray rising and peaking timescales are comparable to those of the optical/UV flares.
Figure 2. The 0.2–10 keV pn (red) and combined MOS (black) spectra obtained from XMM pointed (red) observations in 2013, and the pn spectrum (green) from the XMMSL in 2005. The XMM pointed pn and combined MOS spectra are fitted simultaneously with an absorbed power-law model and the XMMSL spectrum is fitted with a blackbody model, as described in Section 2.1.1.

Figure 3. X-ray light curve of XMMSL1 J1319+2259 as the luminosities in 0.2–2 keV (circles) and upper limits (arrows). A $t^{-5/3}$ decline law is fitted to the detected data points: $L(t) = L_{1\,\mathrm{yr}} \times \left[\frac{t - t_0}{1\,\mathrm{yr}}\right]^{-5/3}$ erg s^{-1}, where t_0 is the tidal disruption time and $L_{1\,\mathrm{yr}}$ is the luminosity 1 yr after the disruption. The best-fit parameters are shown in the figure, and the solid curve is the curve predicted for the decline stage. The dashed line shows the disruption time (t_0) obtained from the fitting. The region in light gray shows the range of the peak luminosity assuming that the flare began to decrease at an epoch from 1 to 3 months after the disruption.

UV, the SDSS in optical, the Two-Micron All Sky Survey (2MASS; Skrutskie et al. 2006) in near-infrared (NIR), and the all-sky survey performed by *WISE* in mid-infrared (MIR). The galaxy was also observed by the optical/UV instruments on board *XMM-Newton* and *Swift* during the X-ray pointed observations. An optical spectrum was taken in the SDSS in 2008. Information of the multiwavelength observations, from far-UV (FUV) to IR, and the photometry results are

summarized in Table 3. In this section, we describe the data reduction and analysis, and some of the technique details can be found in the Appendix for each of the instruments.

3.1. Optical Imaging and Photometric Data Analysis

3.1.1. SDSS Imaging Data

NGC 5092 was observed for broadband photometric imaging in the u, g, r, i, z bands in the SDSS on 2005 March 10 (run 5183, camcol 6, field 441) and 2005 April 2 (run 5224, camcol 1, field 299). The detailed data analysis can be found in Appendix A.2.1, and the obtained magnitudes of the galaxy are listed in Table 3. The two SDSS imaging observations, performed near the inferred epoch of the tidal disruption, can also be used to examine any possible optical flare using the image subtraction method. Compared to the 2005 March 10 images, there is a clear excess in the core of the galaxy in the 2005 April 2 images, indicating a brightening, and thus a nonstellar process in the nuclear region (see Figure 4). To quantify this possible flare, we decompose the nuclear emission from the host galaxy for the drC images using the 2D imaging analysis tool GALFIT (Peng et al. 2002). Figure 5 shows, for the u band as demonstration, the resultant model and residual images from the image decomposition, as well as the radial profiles of the surface brightness and their model components of the galaxy. The fitted parameters of the nuclear emission (point-spread function [PSF]) and the galactic components are summarized in Table 4. The fitted positional offset of the flare and the nucleus is only subpixel (0$\farcs$396 per pixel), or less than 150 pc. We thus consider the optical flare to have most likely originated from the central SMBH. Please refer to Appendix A.2.1 for the details of the image subtraction and decomposition.

Note. This table gives the aperture photometric magnitude of the whole galaxy in multiple bands within the apertures of radii listed in the last column. All the magnitudes are in the AB magnitude system.

3.1.2. XMM OM and Swift UVOT Data

During the *XMM-Newton* observation in 2013, the source was also observed with the Optical/UV Monitor (OM; Mason et al. 2001) in `image` mode using the *U* filter, which is centered at 3440 Å. The observation was split into five parts with exposures of 1120 s in length for each. We present the detailed analysis in Appendix A.2.2 and summarize the photometric results in Table 5 for each exposure. We then take the mean and standard deviation of the five exposures as the aperture AB magnitude measurement of the galaxy, which is 15.67 ± 0.01.

The Ultraviolet/Optical Telescope (UVOT; Roming et al. 2005) observations were obtained in *U* (3465 Å) and UVW1 (2600 Å) (Poole et al. 2008) bands in `image` mode during the *Swift* observation in 2018. We measure the aperture magnitude using the UVOT software task `uvotsource` and present the results in Table 3. Compared to the SDSS observation in 2005, the source was about 1 mag fainter in the *U* band.

3.2. GALEX UV Data

The galaxy NGC 5092 was also imaged and detected by *GALEX* three times in near-UV (NUV, 1771–2831 Å) on 2005 May 28, 2005 June 11, and 2007 May 6 and once in FUV (1344–1786 Å) on 2007 May 6. The NUV imaging observations, performed from just a few months to 2 yr after the tidal disruption, provide valuable data to examine any UV radiation of the nucleus possibly associated with the X-ray flare. We perform image subtraction on the calibrated NUV images between the 2005 May and 2007 observations and find the nuclear emission to be much brighter in 2005 than in 2007 (see Figure 6), indicating an NUV flare originating from the activity of the SMBH, likely associated with the X-ray flare. To quantify the amplitude of the variability, the fluxes of the entire galaxy are measured from the reduced images by using gPhoton (Million et al. 2016) tool gAperture, with a

photometry aperture of 20″. The aperture magnitudes for all three NUV observations and the one FUV observation are presented in Table 3. Compared to the 2007 observation, the source was brighter by ~3 mag in the NUV band in 2005. Details of the aperture photometry and image subtraction are described in Appendix A.3.

3.3. A UV–Optical Flare

Figure 7 shows a summary of the photometric results of the galaxy NGC 5092 obtained above taken in various optical and UV bands (without Galactic extinction correction). Clearly, the *GALEX* NUV and optical *u(U)* fluxes dropped significantly by about 3 and 1 mag, respectively,[11] on timescales of a few years or longer. Now we study the quasi-simultaneous optical–UV spectra of the flare, which were taken 1–2 months apart. The optical luminosities of the galactic nucleus are calculated at the central frequencies of the five SDSS filters. To do this, the PSF fluxes derived from the 2D image decomposition in Section 3.1.1 are used for the 2005-03 and 2005-04 observations, which are assumed to be dominated by the flare emission. The resulting optical spectra of the flare at the two epochs are shown in Figure 8. The two spectra can be well fitted with a blackbody model with temperatures of $1.6^{+1.3}_{-0.5} \times 10^4$ K (2005-03) and $1.7^{+1.9}_{-0.6} \times 10^4$ K (2005-04) (90% uncertainties), respectively. The relatively large uncertainties are due to the fact that the peak or turnover of the spectrum is not sampled by observations. We also calculate the ultraviolet luminosity of the flare from the *GALEX* NUV photometry by subtracting the galaxy contribution, which is estimated from the SED fitting of the galaxy starlight (see Section 5.4). The luminosities at 2305 Å for the 2005-05 and 2005-06 observations are overplotted in Figure 8. Assuming that the luminosities did

---

[11] Although the bandpasses of three filters SDSS-*u*, OM-U, and UVOT-U are not the same, we find that differences among their measured magnitudes are less than 0.2 by comparing stars in the fields of view of the observations.
Figure 4. From left to right, cutouts of SDSS u-band images in 2005-03 and 2005-04 observations and the residual image with a size of 350×350 pixels centered on NGC 5092. The two data images are convolved with a Gaussian profile with FWHM = 4″45 and 4″43, respectively, so that the smoothed images have matching PSFs in FWHM. The residual image is obtained by subtracting the image on 2005 March 10 from that on 2005 April 2.

not vary significantly between 2005-04 and 2005-05, we fit jointly the optical and NUV luminosities with a single blackbody, resulting in a temperature of $2.4^{+0.6}_{-0.3} \times 10^4$ K. A power law can also give a good fit to the data, with $\Gamma \sim 0.2$. Thus, the observed optical–UV flare emission around March–April, if assumed to be a blackbody, had a temperature of $\sim(1\text{--}2) \times 10^4$ K, consistent with those in previously reported optical TDEs (van Velzen 2018). The integrated optical–UV luminosities, from 100 to 10000 Å, of the flare are estimated to be around $\sim(2\text{--}6) \times 10^{43}$ erg s^{-1}, corresponding to an Eddington ratio of $\sim(3\text{--}9) \times 10^{-3}$.

We note that the possible existence of a weak, AGN-like activity in the galaxy cannot be ruled out (see Section 4), which might contribute to the PSF fluxes. While in u band, the whole galaxy in 2005-04 was about 1 mag brighter than that in the UVOT observation in 2018, suggesting that the PSF flux in at least the u band must be dominated by the flare. The blackbody temperature calculated by using only the u-band PSF flux in 2005-04 and the NUV in 2005-05 is $\sim$35,000 K, also in the range of those previously reported TDEs.

3.4. WISE and 2MASS

In the MIR band, NGC 5092 was bright enough to be detected in a single exposure with *WISE* in the *W1* (3.4 μm) and *W2* (4.6 μm) bands. We analyzed the *WISE* observational data for NGC 5092, which were taken from 2010 to 2018, and extracted light curves with 12 time bins in the two wavebands. The details of the data analysis are described in Appendix A.4. The MIR light curves are overplotted in Figure 7, which show a trend of fading over a time span of about 6 yr and appear to remain mostly constant in the observations of the last several epochs. To estimate the contribution from the host galaxy, we consider the last five epochs for *W1* and the last one epoch for *W2* as the quiescent state, which have averaged magnitudes of $W_1 = 13.73 \pm 0.01$ and $W_2 = 13.68 \pm 0.01$. Assuming that the emission in the *W1* and *W2* bands originates from a blackbody, we calculate the temperatures in each epoch using the host-galaxy-subtracted fluxes. We find that the temperatures spread in the range of $\sim$600–1500 K, consistent with those of the previously reported TDE IR echoes (Komossa et al. 2009; Dou et al. 2016, 2017; Jiang et al. 2016, 2017; van Velzen et al. 2016; Wang et al. 2018). We also obtained the NIR JHK_S

images from 2MASS and measured the aperture magnitudes as shown in Table 3.

4. Optical Spectral Analysis

An optical spectrum of NGC 5092 was obtained by the SDSS on 2008 February 11, which is about 3 yr after the optical/UV flare. The fiber was centered at the nucleus of the galaxy with a radius of 3″. Figure 9 shows the spectrum of NGC 5092, which is dominated by host starlight. There seem to be no apparent emission lines in this spectrum by visual check. Hence, it necessitates proper model and subtraction of the stellar continuum to examine possible weak emission-line features. Generally, we conducted the continuum fitting following the procedures described in Zhou et al. (2006); for details see Appendix A.5.1. As shown in Figure 9, the galaxy starlight model (orange) gives a reasonable fit to the optical spectrum (black), with a dominant middle-aged stellar population of 2.5 Gyr. The best-fit stellar velocity dispersion is $\sigma^* = 156 \pm 26$ km s^{-1} (corrected for instrumental broadening of 56 km s^{-1} as measured from arc spectra and tabulated by the SDSS). We can thus estimate the mass of the central BH of the galaxy from σ^* using the formalism of Ferrarese & Ford (2005):

$$M_{\mathrm{BH}} = 1.66(\pm 0.24) \times 10^8 \, M_\odot \left(\frac{\sigma^*}{200 \text{ km s}^{-1}} \right)^{4.86(\pm 0.43)}, \quad (3)$$

yielding $M_{\mathrm{BH}} = 5.0^{+5.6}_{-2.9} \times 10^7 \, M_\odot$.

After removing the continuum, several narrow emission lines, including [O III] and Balmer lines, are found in the residual spectrum, and no broad-line features are detected. The fitting methods are detailed in Appendix A.5.2. Among these emission lines, [O III] λ5007 and Hα are detected with a signal-to-noise ratio (S/N) of >3, and Hβ is marginally detected with S/N = 2.4. Note that, apart from the statistical uncertainty in the line fitting, the uncertainty introduced by continuum subtraction has also been considered in the estimation of S/N; for details see Appendix A.5.2. The line measurements, including the fluxes and equivalent widths (EWs), are summarized in Table 6, and the EWs are consistent with those given by MPA-JHU catalogs[12] based on the methods of Brinchmann et al. (2004), Kauffmann et al. (2003b), and

Tremonti et al. (2004), e.g., 1.8 ± 0.4 versus 2.0 ± 0.1 for EW ([O III]λ5007), 1.1 ± 0.3 versus 0.8 ± 0.1 for EW (Hα).

The narrow-line diagnostic diagram, the so-called BPT diagram (Baldwin et al. 1981), is used to investigate the mechanism of the line emission. As [N II] $\lambda\lambda$6548, 6583 and [S II] $\lambda\lambda$6716, 6731 are not robustly detected, their flux upper limits (see Appendix A.5.3 for details) are adopted to calculate the line ratios. The locations of NGC 5092 on the diagram of [O III] λ5007/Hβ versus [N II] λ6583/Hα and [O III] λ5007/Hβ versus [N II]/Hα are shown in Figure 10. As can be seen, the location of the line ratios of NGC 5092 is close to the boundaries among the AGN, LINER, and star formation regions. Given the relatively large uncertainties of the line ratios due to the weakness of the lines, a reliable classification of emission-line mechanism is hard to achieve, though the [O III]/Hβ–[N II]/Hα diagram may hint at a low-ionization nuclear emission-line region (LINER).

5. Discussion

5.1. XMMSL1 J1319+2259: A TDE in NGC 5092

The X-ray source XMMSL1 J1319+2259, with a 0.2–2 keV luminosity of $\sim 9 \times 10^{42}$ erg s^{-1} as detected in the XMMSL in 2005-07, brightened by a factor of >20 as compared with the previous RASS upper limit, and faded to a flux ~ 240 times fainter when it was reobserved 8 yr later. The X-ray spectrum of the flare is very soft and can be described with a blackbody at $kT \sim 60$ eV, with an overall luminosity of $\sim 1.5 \times 10^{43}$ erg s^{-1}. The features are hardly explained by a supernova but resemble those of X-ray TDEs reported previously. Assuming a $t^{-5/3}$ law of flux decline characteristic of TDEs, the disruption time is derived to be around 2005 February to April, and the 0.2–2 keV peak luminosity around $(1–7) \times 10^{43}$ erg s^{-1}, assuming that the flux began to decrease from 1 to 3 months after the disruption. Interestingly enough, an optical–UV flare is also found to occur at the galactic nucleus around the epoch of the X-ray flux, suggesting their physical association. The optical–UV flare can be fitted with blackbody radiation at a temperature of $\sim(1–2) \times 10^4$ K. Assuming a spherical geometry, following the Stefan–Boltzmann law, the sizes of the optical/UV and X-ray emission regions are around $100R_g$ and several R_g, respectively, where R_g is the gravitational radius ($R_g = \frac{GM_{\rm BH}}{c^2}$) for the derived BH mass of $\sim 5 \times 10^7 M_\odot$ from the $M_{\rm BH}$–σ^* relationship. Besides, the continuous decline in the MIR fluxes of the galaxy in the WISE W1 and W2 bands from 2010 to 2018 can be naturally attributed to the dust-reprocessed light of the flare at higher energy bands (Jiang et al. 2016; Lu et al. 2016; van Velzen et al. 2016). All these features are characteristic of TDEs observed previously, which we consider to be the most likely interpretation for this object, albeit the sparse data sampling.

The X-ray emission as observed with XMM-Newton in 2013 had a much lower luminosity of $\sim 3 \times 10^{40}$ erg s^{-1}, and the spectrum became much harder with $\Gamma = 2.1$. At such a low luminosity level, the contribution from the host galaxy may not be negligible. Assuming that only 10% of the observed flux comes from the TDE process, the derived tidal disruption time would be around 2006-06 and the derived peak luminosity in 0.2–2 keV is $\sim 10^{43}$ erg s^{-1}. Although the derived disruption time might be later than the optical/UV brightening, we note that it is subject to large uncertainty, as it depends on the estimation of the flux and the assumed decline law. XMMSL1 J1319+2259 is a rare example of a TDE candidate that shows contemporaneous X-ray and optical flares, while the majority of observed TDEs were detected either in optical/UV or in X-ray. According to Dai et al. (2018), the diversity could be interpreted by a unified model where the spectral properties of the TDE depend mainly on the viewing angle with respect to the orientation of the disk.

5.2. AGN Variability?

Although all the observed properties of XMMSL1 J1319 +2259 and its associated multiwavelength flares are typical of the previously reported TDEs, the possibility of AGN variability may not be ruled out completely, due to the possible existence of weak nuclear activity in the host galaxy, as revealed from the ratios of the weak emission lines shown in the optical spectrum of the galaxy. Radio emission, which is commonly used to be an important diagnostic of AGN activity, is not detected in NGC 5092 either in the Faint Images of the Radio Sky at Twenty cm (FIRST; White et al. 1997) or in the NRAO VLA Sky Survey (Condon et al. 1998) database, with the upper limit given by FIRST to be 0.2 mJy. We note that the

X-ray emission of NGC 5092 at the nonflaring states is rather weak, e.g., $L_{0.2-2\,\mathrm{keV}} \sim 3 \times 10^{40}\,\mathrm{erg\,s^{-1}}$ from the *XMM-Newton* pointed observation in 2013. Such a luminosity is comparable to typical X-ray emission from inactive galaxies, which can be estimated from the NIR fluxes (2MASS *H* bands) to be $L_X \sim 6 \times 10^{39}\,\mathrm{erg\,s^{-1}}$, with a standard deviation of 0.5 dex, using the X-ray–NIR luminosity relation for early-type galaxies (Ellis & O'Sullivan 2006). This sets a strong constraint that even if there exists a nuclear activity in NGC 5092, it has to be rather weak. This is also supported by the *W1–W2* color from the *WISE* measurements, which indicates the lack of a strong AGN in NGC 5092.

However, analysis of the optical spectrum taken in 2008, about 3 yr after the disruption event, shows that NGC 5092 may be located in the Seyfert/LINER regime in the BPT diagram, although the classification is rather uncertain owing to the large uncertainties in the measured line ratios. Assuming that the narrow emission lines, [O III] and Hα, are from the persistent weak AGN radiation, the expected AGN luminosity is $L_{0.2-2\,\mathrm{keV}} \sim 6 \times 10^{40}\,\mathrm{erg\,s^{-1}}$, comparable to that measured with the *XMM-Newton* observation in 2013, based on the relation between the X-ray luminosities and optical emission lines for local AGNs[13] (Panessa et al. 2006). Thus, the possibility cannot be ruled out that this galaxy hosts a weak AGN. However, the very soft X-ray spectrum at the flaring state ($\Gamma \sim 4$), as well as the spectral hardening with time, is typical of TDEs rather than AGNs. Furthermore, those weak emission lines ([O III] and Hα) are found to be relatively broader (FWHM $\sim 900\,\mathrm{km\,s^{-1}}$) than those of most AGNs (Zhang & Hao 2018), which may be explained as originating from the TDE process. In this work we argue that the observed flare in the X-ray and multiple wavebands originated most likely from a TDE, although an extreme AGN variability event of a possible weakly active nucleus in NGC 5092 cannot be ruled out.

5.3. Infrared Echo

The *WISE* observations show a continuous decline in the MIR light curves as described in Section 3.4. Similar flaring and fading in the MIR light curves have also been found in several TDEs (Dou et al. 2016, 2017; Jiang et al. 2016, 2017; van Velzen et al. 2016; Wang et al. 2018), which is explained as emission from dust in the nuclear region by reprocessing the high-energy radiation of the TDE. Such an echo radiation lags

the primary radiation by a delay time of approximately R/c, assuming the central symmetric geometry of the irradiated dust, with a distance R to the central source and where c is the speed of light. The echo luminosity depends on the bolometric luminosity of the primary radiation and the covering factor of the dust subtended to the central source.

We consider the MIR light curves observed in NGC 5092 with *WISE* as the fading echo of dust irradiation of the TDE flaring, and we attempt to reproduce them with a simple model. We assume that the bolometric luminosity of the TDE L_{TDE} decreases with time as $t^{-5/3}$ as the X-ray luminosity L_X does, and the energy absorbed by the dust is completely reradiated away. The IR luminosity L_{IR} is calculated as L_{TDE} multiplied by the covering factor of the irradiated dust C_f, with a time lag t_d,

$$L_{\mathrm{IR}}(t) = L_{\mathrm{TDE}}(t - t_d) * C_f = L_X(t - t_d) \times \frac{L_{\mathrm{TDE}}}{L_X} \times C_f, \quad (4)$$

where L_{TDE}/L_X is the bolometric correction factor in the X-ray band of the TDE and is assumed to be constant over time. The luminosities in the *W1* and *W2* bands can be calculated by assuming the dust emission to be blackbody with an effective temperature T_{dust}. As described in Section 3.4, the temperatures are found to lie in the range of 600–1500 K. As the first-order approximation, we try to reproduce the light curves in the *W1* and *W2* bands by fitting them jointly with a simple model assuming a constant temperature of 1000 K. We calculate the monochromatic luminosity in the *W1* and *W2* bands as

$$\nu_i L_{\nu_i}(t) = L_{\mathrm{IR}}(t)/n_i + L_{0i}, $$
$$(i = 1 \text{ for } W1 \text{ band}, i = 2 \text{ for } W2 \text{ band}), \quad (5)$$

where L_{0i} is the luminosity of the host galaxy and $L_{01} = 1.6 \times 10^{43}\,\mathrm{erg\,s^{-1}}$ for *W1* and $L_{02} = 7.2 \times 10^{42}\,\mathrm{erg\,s^{-1}}$ for *W2* (see Section 3.4), and n_i is the correction factor at the frequency ν_i at the temperature T_{dust}. For $T_{\mathrm{dust}} = 1000\,\mathrm{K}$, the ratio between n_1 and n_2 is $n_1/n_2 = 0.9$. From Equation (5) we have

$$\nu_i L_{\nu_i}(t) = A_i \times L_X(t - t_d) + L_{0i}, \quad (i = 1, 2) \quad (6)$$

where the time lag t_d and $A_i = \frac{L_{\mathrm{TDE}}}{L_X} \times C_f/n_i$ are both free parameters (with $A_2/A_1 = 0.9$). We fit the model to the *W1* and *W2* data jointly by minimizing χ^2. The best-fit parameters are $t_d = 2.5 \pm 0.1\,\mathrm{yr}$, $A_2 = 15.1 \pm 1.1$, and the fitting result is plotted in Figure 11. Although the model is oversimplified, it can well reproduce the observed light curves of both *W1* and

---

[13] Please note that although the correlations between X-ray and optical emission lines are of relatively large scatter, the luminosity in the *XMM-Newton* pointed observation in 2013 is comparable to that expected from the best-fit correlations.
Figure 6. Top: *GALEX* NUV images of NGC 5092 on 2005 May 28 (left) and 2007 May 6 (right) with size of 341 × 341 pixels centered on NGC 5092. Bottom left: residual image derived by subtracting the NUV image on 2007 May 6 from that on 2005 May 28. Bottom right: zoom-in version of the residual image with a size of 25 × 25 pixels. The red and green plus signs on the zoom-in residual image show the center of the residual image and the optical center of the galaxy, respectively.

W2, indicating that the observed MIR flare may be explained by the reradiation of TDE primary photons by dust. To obtain a better constraint on the dust distribution and richness around the BH, well-covered light curves and accurate measurement of the TDE SED are needed.

5.4. Host Galaxy

We perform host galaxy SED fitting with fluxes in *ugriz* bands derived by subtracting the PSF fluxes from the aperture fluxes of the SDSS 2005-04 observation. The fluxes are corrected for the Galactic extinction by employing the IDL code fm_unred.pro with $E(B-V) = 0.014$ (Schlegel et al. 1998), assuming the Milky Way (MW) extinction curve (Gordon et al. 2003). The code we use for galaxy SED modeling is model package Multi-wavelength Analysis of Galaxy Physical Properties (MAGPHYS), a self-contained, user-friendly model package to interpret the observed SED of galaxies in terms of galaxy-wide physical parameters pertaining to the stars and the interstellar medium, following the approach described in da Cunha et al. (2008).

The galaxy SED thus obtained using the SDSS imaging photometric data only is compared with the measurements in the other bands analyzed in Section 3. It is found that all the measurements match the extrapolation of the galaxy SED well

except for the two *GALEX* NUV fluxes in 2005, which clearly show excesses as contributed by the nuclear flare. We thus repeat the SED fitting using all the photometric data available for the galaxy except for the *GALEX* NUV ones. This leads to a good fit, as shown in Figure 12. The fitted stellar mass $M_{\rm stars} = 7.5^{+2.3}_{-1.7} \times 10^{10} \ M_\odot$ (68% conf.), and star formation rate SFR $= 0.2 \pm 0.1 M_\odot \ \rm yr^{-1}$ (68% conf.). The SED modeling shows that there are five random bursts experienced by the galaxy, with the last burst of star formation ending 1.89 Gyr ago. With the relationship between BH mass and bulge $K_{\rm s}$-band luminosity (Marconi & Hunt 2003), we obtain a BH mass of $1.06 \times 10^7 \ M_\odot$ using the point-source 2MASS magnitude of $m_{K_{\rm s}} = 11.51$, with a systematic error of 0.3 dex ($2 \times 10^7 M_\odot$), which is consistent with that derived from the $M_{\rm BH}$–σ^* relationship. The optical spectral fitting shows that the starlight of NGC 5092 is dominated by a middle-aged stellar population of 2.5 Gyr. For NGC 5092, the Lick index H$\delta_{\rm A}$, which is optimized for the stellar absorption from A stars (Worthey & Ottaviani 1997), is -1.7 ± 0.6 Å, and the EW of the Hα emission line after correcting the stellar absorption is 1.1 ± 0.3 Å. By analyzing the host galaxy spectra of eight optical/UV TDEs and comparing their features to the SDSS main galaxy spectroscopic sample, French et al. (2016) find that six of eight TDE host galaxies, but only 2.3% of local galaxies, have H$\delta_{\rm A}$> 1.31 Å, suggesting that TDEs may prefer
Figure 7. Multiwavelength photometric results of the entire galaxy NGC 5092 from IR to X-ray. All IR to UV magnitudes are in units of the AB magnitude system (left scale), and X-ray 0.2–2 keV fluxes are shown in erg s^{-1} cm^{-2}. Note that the data are not corrected for Galactic extinction and error bars are in some cases smaller than the points. The dashed lines are used to connect the data points in the same filter and do not trace the decline law.

the rare class of "E+A" galaxies, which are consistent with a post-starburst history. Compared with the TDE host galaxies discussed in French et al. (2016), NGC 5092 is redder and dominated by older stellar population, with Hδ_A = −1.7 ± 0.6 Å. French et al. (2017) show that on the WHAN (Cid Fernandes et al. 2010) diagram, at least five of eight TDE host galaxies lie in the LINER-like region. This is not surprising owing to the possibility that interactions with the gas disk can increase the TDE rate by a factor of 10 (Kennedy et al. 2016), and NGC 5092 is also located around the LINER-like region in the WHAN diagram.

6. Summary

We present and analyze the multiwavelength photometric and spectroscopic observations of the TDE candidate XMMSL1 J1319 +2259 discovered in the *XMM-Newton* Slew survey in 2005-07, which shows contemporaneous flaring in both X-ray and optical/UV bands. The source faded by a factor of ∼240 in the X-ray 0.2–2 keV band, about 1 mag in the optical band when it was reobserved 8 yr later, and 3 mag in the NUV band 3 yr later. The X-ray spectrum of the flare is soft and can be modeled with a blackbody at $kT \sim 60$ eV with an overall luminosity of ∼1.5 × 10^{43} erg s^{-1} ($L_{0.01-100\,keV}/L_{Edd} \sim 2.4 \times 10^{-3}$). In the optical– UV band, the emission kept rising from 2005-03 to 2005-06 and can be modeled with a blackbody at $T \sim (1-2) \times 10^4$ K, with a luminosity of ∼(2–6) × 10^{43} erg s^{-1} ($L_{100-10000\,Å}/L_{Edd} \sim (3 - 9) \times 10^{-3}$), suggestive of an emission region of ∼100R_g in radius assuming a spherical geometry. Since the XMMSL observation in 2005-07 is in the decline stage of the flare, the Eddington ratio during the UV observation in 2005-05 should be $\gtrsim 0.01$. There was also a delayed continuous decline in the *WISE* infrared fluxes, from 5 to 13 yr after the disruption, which can be described with a simplified infrared echo model with a dust temperature of 1000 K. The host galaxy NGC 5092 is an early-type galaxy with a dominant stellar population of 2.5 Gyr, older

than that of the favorable "E+A" type as suggested for TDE host galaxies (French et al. 2016). The mass of the central BH is estimated to be ∼5 × $10^7\,M_\odot$ from the M_{BH}–σ^* relationship. Analysis of the optical spectrum taken 3 yr after the flare reveals faint emission lines, which locate the galaxy at the borderline between AGN, starburst, and LINER in classification diagrams. While this does not allow unambiguous optical classification at present, we also cannot rule out the possibility that the emission lines are actually not permanent, but were excited by the flare itself. We attribute the flare in the X-ray and optical/UV bands to a tidal disruption process, given the large-amplitude variabilities in multiple bands in the galactic nucleus and the ultra-soft outburst X-ray spectrum. XMMSL1 J1319+2259 is among the several TDEs that are detected to show bright flaring in both UV/optical and X-ray bands. Although containing few data points, TDEs discovered from archival data still provide important implications for statistical study, such as the event rate, the luminosity function, and the unification TDE model, as well as their host galaxy properties. To discover larger samples of TDE, especially in real time, future high-cadence time-domain surveys are needed, such as the Large Synoptic Survey Telescope in optical (LSST; Ivezic et al. 2008) and the *Einstein Probe* mission in the soft X-ray band (EP; Yuan et al. 2016a, 2016b).

Appendix
Reduction and Analysis of the Multiwavelength Data

In this appendix, we present detailed accounts of the data reduction and analysis in the X-ray (Appendix A.1), optical (Appendix A.2), UV (Appendix A.3), and infrared (Appendix A.4). The details of the spectral analysis are described in Appendix A.5.
Figure 8. Galactic-extinction-corrected optical–UV spectra of XMMSL1 J1319+2259. The black and red circles represent the PSF fluxes derived from 2D image decomposition of SDSS 2005 March 10 and 2005 April 2 images with GALFIT, respectively. The black and red solid lines are the best-fit blackbody curves for these two observations, respectively. The purple and green stars are *GALEX* NUV data on 2005 May 28 and 2005 June 11, respectively, after subtracting the host galaxy contribution. The purple dashed line shows the best-fit blackbody using the SDSS data on 2005 April 2 and *GALEX* NUV data on 2005 May 28.
Figure 9. Optical spectrum of NGC 5092 obtained in SDSS on 2008-02-11. Flux calibrated data are shown in black, and the stellar population model is shown in orange. The starlight-model-subtracted spectrum is shown in orange in the bottom panel.

A.1. X-Ray Data

We perform the *XMM-Newton* data reduction following the standard procedures with the software *XMM-Newton* Science Analysis System (SAS version 16.0.0). XMMSL1 J1319+2259 was discovered in slew 9102500005 from XMM revolution 1025. With the slew data files (SDFs) downloaded from the *XMM-Newton* science archive,[14] the calibrated photon event files for pn are produced with SAS task eslewchain. Since the source did not suffer from pileup problems in this observation, the pn spectrum was extracted with patterns 0–4. The source spectrum has been extracted from a circle of radius 30″, and a region of

the same size was used for the background. The technique described in Read et al. (2008) was used to create the ancillary file, and the canned response file *eps_ff*20_*sdY*6_*v*6.9.*rmf* was used for the redistribution matrix.

The *XMM-Newton* pointed observation was carried out on 2013 December 21, with all three *XMM-Newton* EPIC cameras operating in the Full Frame (FF) mode and the thick filter in place. With the observation data files (ODFs), the calibration files and calibrated photon event files for pn and MOS are produced with the tasks epchain and emchain. Source photons are extracted from a circular region with a 30″ radius centered on the object, and background counts from a 60″ circular source-free region on the same CCD chip. High background periods (count rates greater than 0.4/0.35 counts s^{-1} for the pn/MOS camera) caused by high-energy protons in orbit are filtered by creating good time intervals. The pn spectrum is extracted from X-ray events with patterns from 0 to 4 and the MOS spectra from 0 to 12. Ancillary files and response matrices are generated using the arfgen and rmfgen SAS tasks, respectively.

A.2. Optical Data

A.2.1. SDSS Optical Data

In the two SDSS observations taken on 2005 March 10 and 2005 April 2, the psField files[15] and the drC images[16] are

---

[14] http://nxsa.esac.esa.int/nxsa-web

[15] File with preliminary photometric calibration, as well as final PSF fit, for a single field in an imaging run, which provides the 2D reconstruction of the PSF.

[16] The corrected image frame, having been bias subtracted, flat-fielded, purged of bright stars, and header updated with the latest calibrations.

Table 6
Optical Emission-line Measurements

	[O III]λ5007	Hα	Hβ	[N II]λ6583	[S II]λ6717	[S II]λ6731
Flux (10^{-17} erg s^{-1} cm^{-2})[a]	382.4 ± 78.8	268.5 ± 78.8	186.2 ± 78.8	<94.2	<54.2	<126.0
Equivalent width (Å)[b]	1.8 ± 0.4	1.1 ± 0.3	0.9 ± 0.4	>0.4	>0.2	>0.6

Notes.

[b] Equivalent widths of the emission lines after correcting stellar absorption.

retrieved from the SDSS Data Archive Server.[17] All the SDSS drC images have a "soft bias" of 1000 data numbers (DNs) added, so they can be stored as unsigned integers, as described in the SDSS image processing pipeline (Lupton et al. 2001). With the reduced drC images, the aperture fluxes of the galaxy are measured using Source Extractor (SExtractor, version 2.25.0; Bertin & Arnouts 1996) within the aperture radii listed in the last column in Table 3, which are chosen in such a way that the surface brightness beyond the radius does not change with the radial distance to the galactic center. The image subtraction process is as follows: taking the u-band images as an example, the PSF of the observed images is accessed by fitting the surface brightness of the unsaturated stars in the field of view with a two-Gaussian model, giving an FWHM (full phrase) of 1″47 and 1″58 for the 2005-03 and 2005-04 images, respectively. The images in the 2005-03 and 2005-04 observations are convolved with Gaussian profiles of FWHM = 4″45 and 4″43, respectively, to have matching PSFs, resulting in smoothed images with nearly identical PSFs of 4″59 in FWHM. The 2005-03 images are then scaled to the flux level of the 2005-04 images according to the counts measured of the nearby stars. The residual images are generated by subtracting the rescaled 2005-03 images from the 2005-04 images. The convolved images and the residual image after subtraction are shown in Figure 4. There is a clear excess in the core of the galaxy in the 2005-04 image compared to that in 2005-03, indicating brightening of the optical light, and thus a nonstellar process in the nuclear region.

To quantify this optical flaring emission, we decompose the nuclear emission from the host galaxy for the drC images using the 2D imaging analysis tool GALFIT (Peng et al. 2002). The exact information about the PSF for each image is written out to the relevant psField files. We use the standalone code, read_PSF, from the READATLASIMAGES-V5_4_11 program,[18] to reconstruct the PSF at the position of the galaxy NGC 5092 in the frame. The obtained PSF image has a standard size of 51 pixels on each side, and the background level is set to the standard soft bias of 1000 DNs. For each drC image, a cutout of 200 pixels on each side centered on the core of NGC 5092 is used to ensure that enough pixels are retained to properly determine the background. The 1000 DN soft bias is removed from the cutouts and PSF images prior to fitting.

The background is calculated by selecting a source-free region and is always included. The host galaxy is modeled with an exponential disk and a Sérsic bulge (the index fixed at 4). A point-like source, modeled by the PSF of the images, is added to account for any nonstellar nuclear emission. For the 2005-03 observation, the stellar components (exponential disk and Sérsic) are fixed to those fitted from the 2005-04 observation in

all bands. Such a model gives acceptable fits to all the images by visually examining the residual images. The estimation of the overall uncertainties of the fitted parameters is nontrivial (only statistical errors are given by GALFIT). As a rough estimation, we compare the total fluxes of the model to the data fluxes for each of the images and find differences $<30\%$. We then simply take 30% as the flux uncertainties of each model component in this work. The offset of the fitted PSF and the nucleus is subpixel (0″396 per pixel), or less than 150 pc.

A.2.2. XMM *OM* and Swift *UVOT* Data

With the ODF downloaded from the *XMM-Newton* science archive, we extract the background-subtracted photometric data using the omichain processing pipeline with the default parameter setting as recommended by the SAS threads. The source partly overlaps the central ring of emission caused by the scattered background light and is larger than the upper limit of the extraction region, a circle with a radius of 24 pixels (corresponding to 11″4), allowed by the interactive photometry task omsource. So we define our own regions using the DS9 tool and perform aperture photometry on the observing science window (OSW) IMAGE files obtained after running the omichain for each exposure. The source is extracted in a circle of 20″ radius, and the background is estimated in a circle with the same size in a source-free region. Coincidence loss, a phenomenon that occurs when the source count rate is high and the detector response is nonlinear (Fordham et al. 2000), is corrected with the correction factor taken from the relevant exposure SWSRLI files. To convert the OM count rates into magnitudes and fluxes, the AB magnitude system for OM implemented by the OM team is used.[19]

For the UVOT observations, we follow the UVOT reduction threads[20] for the data reduction work, with the "Level 2" UVOT FITS files for each of the filters retrieved from the Space Science Data Center[21] used for aperture photometry. Source counts are extracted from regions with a radius of 30″ and 20″ for U and UVW1 images, and a sky region of 40″ radius is used to estimate and subtract the sky background using the UVOT software task uvotsource. To convert the count rates into magnitudes and fluxes, the most recent UVOT calibrations (Poole et al. 2008; Breeveld et al. 2010) are used.

A.3. GALEX *UV* Data

There were three detections with *GALEX* in NUV on 2005 May 28, 2005 June 11, and 2007 May 6 and one detection in FUV on 2007 May 6. To generate calibrated light curves and

---
Figure 10. Location of NGC 5092 on the BPT diagram of [O III] λ5007/Hβ vs. [N II] λ6583/Hα and [O III] λ5007/Hα vs. [S II]/Hβ. In panel (a), the solid and dashed curves are the theoretical line for extreme starburst (Kewley et al. 2001) and the empirical dividing line between star formation and Seyferts or LINER, respectively (Kauffmann et al. 2003a). Sources that lie between the two lines are classified as composite starburst/AGN objects. In panel (b), the solid curve has the same meaning as in panel (a), and the dashed–dotted curve is the Seyfert-LINER line taken from Kewley et al. (2006).

Figure 11. Smoothed *W1* and *W2* light curves of NGC 5092 and the dust reradiation model. The *W1* and *W2* data are shown with blue and red circles with error bars, respectively. Assuming a $t^{-5/3}$ decline law and a constant dust temperature of 1000 K, the reproduced *W1* and *W2* light curves derived from the dust reradiation model are shown with blue and red curves, respectively. Also shown with dashed lines are the contributions from the host galaxy in each band.

Figure 12. Host galaxy SED fitting with MAGPHYS—luminosity vs. wavelength in logarithmic scale. Data points used in the fitting include the *GALEX* FUV and NUV in 2007, OM in 2013, UVOT in 2018, 2MASS in 1999, and galaxy fluxes derived from the SDSS 2005 April 2 images using GALFIT. Also shown in stars are the Galactic-extinction-corrected *GALEX* NUV fluxes in 2005. The black curve represents the best fit to the observed points. The lower part of the figure gives the likelihood distribution of the parameters, stellar mass of the galaxy (M_{stars}), specific star formation rate (sSFR), and star formation rate (SFR).

images for the FUV and NUV observations, gPhoton (Million et al. 2016) is used, which is a suite of publicly available *GALEX* calibration/reduction pipeline software tools written in Python.

We perform image subtraction on the calibrated NUV intensity images, generated with gPhoton image creation tool gMap with 0°.5 angular extent centered on the galaxy NGC 5092, between the 2005 and 2007 May observations. The differential image exhibits a prominent excess—thus a flare in the NUV band—at the nucleus. We measure the position of this excess emission using SExtractor as R.A. = 13ʰ19ᵐ51ˢ.5, decl. = 23°00′00″.0, which is consistent with that of the galactic nucleus (R.A. = 13ʰ19ᵐ51ˢ.5, decl. = 22°59′59″.6) derived from *r*-band SDSS 2D image decomposition with GALFIT as described in Appendix A.2.1, within the positional uncertainty of 0″.5 (Morrissey et al. 2007).

To quantify the amplitude of the variability, we measure the aperture photometry of the entire galaxy with gPhoton tool gAperture. The photometry aperture is a circle of 20″ radius,

and the background is selected from an annular region with inner and outer radii of 25″ and 30″, respectively.

A.4. Infrared Data

The *WISE* has performed a full-sky imaging survey in four bands, *W1* (3.4 μm), *W2* (4.6 μm), *W3* (12 μm), and *W4* (22 μm), from 2010 February to August. *WISE* was in hibernation in 2011 February owing to the depletion of the solid hydrogen cryogen used to cool the *W3* and *W4* instrumentation, and it was reactivated and renamed NEO-WISE-R since 2013 October, using only the *W1* and *W2*. We download the *W1* and *W2* data from the ALLWISE (Wright et al. 2010) and NEOWISE (Mainzer et al. 2014) multiepoch

photometry data release by IRSA.[22] The best-quality single-frame images are used, by selecting only detections with good-quality frame (*qi_fact* > 1), low radiation hints (*saa_sep* > 5), not in the moon masking area (*moon_masked* = 0), without contamination and confusion (*cc_flag* = 0). The data mainly spread in 12 epochs at intervals of about 6 months, with each epoch containing about 12 single exposure observations performed within 1–2 days. To examine the long-term variability in IR, we smooth the light curves by measuring the median magnitudes and take the standard deviations as the magnitude uncertainties in each epoch. The magnitudes are then converted to the source flux density using the equations and parameters on the *WISE* data processing website.[23]

NGC 5092 was also covered in 2MASS (Skrutskie et al. 2006), and the Atlas images in each filter, used for aperture photometry, are accessible via the 2MASS Images Services,[24] which are administered by the Infrared Science Archive (IRSA).[25] To convert the calibrated magnitudes into fluxes, the fluxes for zero-magnitude conversion values from Cohen et al. (2003) are used.

A.5. Optical Spectral Analysis

A.5.1. Starlight Modeling

A series of procedures, which have been developed and applied in our previous work (Lu et al. 2006; Zhou et al. 2006; Liu et al. 2018), are used to deal with starlight and continuum fitting in this work. The starlight is modeled using a combination of six synthesized galaxy templates derived from the spectral template library of simple stellar populations (SSPs; Bruzual & Charlot 2003) using the Ensemble Learning Independent Component Analysis algorithm (see Lu et al. 2006 for details[26]). These templates have included most stellar features in SSPs and hence can avoid underlying overfit in most cases. These templates are broadened by convolving with a Gaussian of an alterable width to match the stellar velocity dispersion of the host galaxy. In addition, the starlight model is slightly shifted in wavelength in adaptive steps to correct the effect introduced by the possible uncertainty of the redshift provided by the SDSS pipeline, which can help to improve the fit and measurement of the host velocity dispersion. During the continuum fitting, two kinds of regions are masked out: (1) bad pixels as flagged by the SDSS pipeline, and (2) wavelength range that may be seriously affected by prominent emission lines. A composite SDSS quasar spectrum introduced by Vanden Berk et al. (2001) is initially adopted to determine the second mask regions. The starlight can be well modeled with a stellar population of 2.5 Gyr, and the fitting result is shown in Figure 9.

A.5.2. Emission-line Measurements

After the subtraction of the stellar continuum, a residual pure emission-line spectrum is obtained, which is fitted as follows. Each of the narrow lines, including Hα, Hβ, [O III], and [N II], is fitted using a Gaussian profile; the profiles and redshifts of

Figure 13. Optical starlight-model-subtracted spectrum in the range of 6500–6650 Å, with the best-fit Hα (orange) and the 90% upper limits of the [N II] emission lines (blue). The inset plot shows the fitted $\Delta\chi^2$ versus the flux of [N II] λ6583, with the horizontal lines indicating the 68% (orange), 90% (red), and 99% (blue) confidence levels, respectively.

these narrow lines are tied to those of narrow [O III], and the flux ratios of [O III] and [N II] doublets are fixed to their theoretical values, respectively. We note that the emission-line-fitting results are vulnerable to continuum subtraction. Thus, in order to check the significance of these emission lines, we try to estimate the uncertainties as described below. We find a series of fake emission-line features from the residual spectrum where there are no prominent emission lines in theory. These so-called emission lines are fitted with one Gaussian, whose widths are fixed to that of [O III]. The standard deviation of the derived fluxes of these fake lines is then taken as 1σ uncertainty of the detected emission lines. As a result, [O III] λ5007 and Hα are significantly detected with S/N > 3, while Hβ is marginally detected with S/N $\approx$ 2.4.

A.5.3. Upper Limit Estimation

For lines of interest without robust detections, upper limits on their fluxes are derived by using the χ^2 fitting technique, following the method used in Li et al. (2015, see their Section 2.1). Here we take the measurement of the flux upper limit of [N II] as an example. The emission-line spectrum segment in a wavelength range covering the [N II]+Hα region (6500–6650 Å) is used only. First, the line complex is modeled with a Gaussian for Hα and two Gaussians for the [N II] doublets. The spectral segment is fitted with this model by using the χ^2 fitting procedure, resulting in the minimum $\chi^2_{\min}$ and a set of best-fit parameters. We then vary the flux of [N II] over a wide range with an increment and fix it in a series of fits, resulting in a series of gradually increasing χ^2 values. The 90% confidence range of the flux is determined by finding the corresponding $\Delta\chi^2 = \chi^2 - \chi^2_{\min} = 2.706$ (for one parameter of interest), which is 9.4×10^{-16} erg s^{-1} cm^{-2} for [N II] λ6583. Figure 13 shows the starlight-model-subtracted spectrum in the wavelength range of 6500–6650 Å, with the best-fit Hα and 90% upper limits of the [N II] emission lines (blue). The inset plot shows the $\Delta\chi^2$ versus the flux of [N II] λ6583, and the orange, red, and green horizontal lines indicate the 68%, 90%, and 99% confidence levels, with $\Delta\chi^2 = 1.0$, 2.706, and 6.63 respectively.

[26] These galaxy templates have been applied in a series of spectral analyses in our previous work (e.g., Zhou et al. 2006; Dong et al. 2012; Liu et al. 2018) and demonstrated to be robust and effective in dealing with a large data set of spectra.
